

The Predictive Power of the Yield Curve across Countries and Time

Abstract

Abstract: In recent years, there has been renewed interest in the yield curve (or alternatively, the term premium) as a predictor of future economic activity. In this paper, we re-examine the evidence for this predictor, both for the United States, and other advanced economies. We examine the sensitivity of the results to the selection of countries, and time periods. We find that the predictive power of the yield curve has deteriorated in the last half of the sample period, although there is evidence of a reversal in the lead-up to the Great Recession. There is reason to believe that European country models perform better than non-European countries when using more recent data. In addition, the yield curve proves to have predictive power even after accounting for other leading indicators of economic activity.

Key words: yield curve, term premium, expectations hypothesis of the term premium, industrial production, recession

JEL classification: C22, E37, E43

Acknowledgments: We thank Shaghil Ahmed, Steve Kamin, Jagjit Chadha, seminar participants at the US Treasury, conference participants at the 10th EABCN conference (Frankfurt, March 30-31, 2009), the 2013 Barcelona GSE Summer Forum, and the Conference on Recent Developments in the Econometrics of Macroeconomics and Finance at the Norges Bank and an anonymous referee for useful comments. Paul Eitelman provided assistance with the data analysis. Lucio Sarno and Catherine Bonser-Neal graciously provided data. The views expressed in this paper are solely the responsibility of the authors and should not be interpreted as reflecting the views of the NBER.

1 Introduction

In 2006, several observers noted the inversion of the yield curve in the United States. That event sparked a resurgence in the debate over the usefulness of the yield curve as an indicator of future economic activity, with an inversion indicating a slowdown (and in some formulations, a recession). The inverted yield curve as recession indicator, while common in the United States, is not widely used in other countries. Moreover, prior to the 2007 recession, there was widespread conviction that – in light of the increased credibility ascribed to monetary policy – the yield curve no longer served as a useful early warning signal for growth slowdowns. Figure 1 displays the yield spread, the difference between long and short term government interest rates, through time for the United States and select advanced economies. The yield spread dips and turns negative prior to each recession period, including the recession beginning in 2007. For European countries, the relationship is not as consistent but there does appear to be some level of coincidence.

The motivation for studying the yield spread is manifold. First, policymakers often need to adjust plans to anticipate future economic conditions. Although policymakers rely on a range of data and methods in forecasting future conditions, movements in the yield curve have in the past provided useful insights, and could still represent a useful tool.

Second, variations in correlation between asset prices and economic activity might inform debates regarding the workings of the macroeconomy. Precisely which countries exhibit a robust relationship between the yield curve and growth might be suggestive of certain channels being important, to the exclusion of others. A similar sort of reasoning applies to examining the goodness of fit over different time periods.

While there is already a voluminous literature on the subject of yield curves and US economic activity, we nonetheless believe now is an opportune time to re-examine the evidence. This conviction is rooted in several developments.

The first is the advent of the euro in 1999. The creation of a more integrated European bond market, and increased economic linkages on the real side, suggests that the old historical

links (or non-links, as the case may be) between the interest rates and output might have changed. Yet, until the great recession, there had not been a sustained and significant downturn in the European economy post-EMU, and hence little opportunity to test the predictive power of the yield curve in this context.

The second is the “conundrum”, i.e., the failure of long-term interest rates to rise along with the short-term policy rate the mid-2000s. Some people ascribed the “conundrum” to the disappearance of risk, variously associated with the cross- country decline in inflation and output volatility – what is sometimes called the Great Moderation – or with greater risk-management on the part of financial institutions. Alternatively, attention has been directed to the demand by pension funds for long-term assets, or foreign central bank purchases of Treasury assets.¹ Regardless of the merit of such arguments, we think it of interest to determine whether the previously extant correlations hold in the more recent period.

Third is the Japanese and the U.S. encounter with the zero lower bound (ZLB). When a country reaches the ZLB, the monetary authority can no longer lower the short-term interest rate and may try to lower long-term rates (which will flatten the yield curve) to stimulate economic growth. Hence, one might expect the relationship between the yield curve and subsequent economic growth to deteriorate when the ZLB is encountered.

The paper is organized in the following fashion. In section 2, we lay out a framework for examining what determines the long term interest rate relative to the short, and relate that to the literature on the yield curve as a predictor of future economic activity. In section 3, we describe the data and the empirical tests we implement. In Section 4, we repeat the exercise using a binary indicator for a recession as the dependent variable. Section 5 explores these relationships using real-time data. Section 6 concludes.

¹See for instance Warnock and Warnock (2006). A contrasting view is in Rudebusch et al. (2006) and Wu (2008).

2 Background

2.1 Theoretical Framework

Following previous literature, this paper focuses on the yield spread defined as the 10-year government bond yield less the 3-month treasury yield (or closest equivalent for countries other than the United States)².

The linkage between the long-term and short-term interest rates can be decomposed thus:

$$i_t^n = \frac{i_t + E(i_{t+1} + \dots + i_{t+n-1} | \Omega_t)}{n} + l_t^n \quad (1)$$

Where i_t^n is the interest rate on a bond of maturity n periods at time t , $E(i_{t+j} | \Omega_t)$ is the expected interest rate on a one period bond in period $t + j$, based on Ω_t , the information available at time t . l_t^n is the liquidity (or term) premium for the n -period bond priced at time t . This specification nests the expectations hypothesis of the term structure (EHTS) (corresponding to the first term on the right hand side of equation 1), and the liquidity premium theory (corresponding to the second term).

The EHTS merely posits that the yield on a long-term bond is the average of the one period interest rates expected over the lifetime of the multi-period bond. The liquidity premium theory allows supply and demand conditions pertaining specifically to bonds of that maturity to affect pricing. The presence of idiosyncratic effects associated with a certain maturity of bond is sometimes linked to the “preferred habitat theory”, the idea that certain investors have a preference for purchasing assets of specific maturities.

Now, for the sake of simplicity, consider the case where l_t^n is small. Suppose expected future short-term interest rates are lower than the short-term rate today. Then the long-term interest rate will be less than the short-term interest rate (i.e., the yield curve inverts). Since low interest rates are typically associated with decreased economic activity, an inverted yield

²Using aggregate Euro area data, Moneta (2003) found that the 10-year/3-month spread specification performed better than any other pair of yield maturities that included two of the following: 3-month, 1-year, 2-year, 5-year, 10-year.

curve could imply an expected downturn. Furthermore, given that $l_t^n > 0$, an inversion should imply a downturn a fortiori.

Why should short interest rates be lower during an economic downturn? The reasoning follows two – not necessarily mutually exclusive - avenues. The first is that decreased economic activity decreases private sector demand for credit. Moreover, the monetary authority has likely decreased the policy rate in response to the slowdown. The second is that the monetary authorities raise rates that precipitate a subsequent slowdown.

2.2 Selective Literature Review

The literature on the usefulness of the yield spread in forecasting future growth is extensive and we review only a subset of the analyses here. Early studies regarding the relationship between growth and the yield spread date to the late 1980s; Harvey (1988, 1989), Stock and Watson (1989), Nai-Fu Chen (1991), Estrella and Hardouvelis (1991) among others, suggested that an inverted yield curve (in this case a negative yield spread) could signal an impending recession. These early studies were primarily conducted using U.S. financial data to predict future Gross Domestic Product (GDP) growth.

While the most simple model requires only a single-variable specification with the yield spread as the lone independent variable, adding the short rate can improve forecasts and may provide at least as much information as the spread itself (Wright, 2006; Ang Piazzesi & Wei, 2006). The specific maturities used to construct the yield spread varies in the literature but empirical evidence suggests using the longest maturity yield to measure the slope of the yield curve (Ang, Piazzesi, Wei, 2006). Models that forecast levels of output growth exhibit a general decline in predictive power since the 1980s, while models that predict binary recession indicators tend to be more stable. The forecasting content of the yield curve may depend on whether or not the economy is responding to monetary shocks. Controlling for structural breaks leads to very different forecasts than models that do not control for such breaks (Chauvet & Potter, 2002, 2005).

Other research focuses on whether the relationship between the yield spread and future economic growth holds in countries other than the United States. Harvey (1991), Davis and Henry (1994), Plosser and Rouwenhorst (1994), Bonser-Neal and Morley (1997), Kozicki (1997), Estrella and Mishkin (1997) and Estrella, Rodrigues and Schich (2003) studied non-US OECD countries using post-1970 data, and generally conclude that the yield spread can be used to some extent in predicting future economic growth. However out-of-sample studies conducted by Davis and Fagan (1997) and Smets and Tsatsaronis (1997) using, respectively, U.S. and German data, and European data, found that parameter estimates are unstable over time and exhibited poor forecasting capabilities.

3 Empirical Model and Results

3.1 Data

The compilation of the dataset confronts the researcher with many choices, including the set of countries to study, and the choice of both regressors and regressand. We selected countries in order to adequately represent the Euro Area. Countries outside the Euro Area provide a basis of comparison to provide perspective and sense of robustness regarding the results.

In addition, to ensure the interest rates represent market-determined rates, we selected countries that have robust and liquid financial markets. The need for a sufficiently large time sample (1970-2013³) further restricted the set of countries we could examine. Given these constraints, we restrict our analysis to Canada, France, Germany, Italy, Japan, the Netherlands, Sweden, the United Kingdom, and the United States.

We select industrial production as our measure of economic activity for the majority of our analysis. While GDP is the broadest indicator of economic activity, the use of industrial production presents some substantial advantages in terms of timeliness and reliability⁴. In

³For Italy and the Netherlands, the data begin in 1971 and 1972 respectively.

⁴By reliability, we mean that the industrial production series do not get revised as significantly as GDP.

any case, growth rates of industrial production tend to follow GDP closely⁵. All of the countries in the data set report industrial production at a monthly frequency while GDP is reported at a quarterly frequency; using IP therefore affords us increased precision. In terms of our recession indicators, we use the NBER measure for the United States and we use the recession indicator from the Economic Cycle Research Institute (ECRI). Yield spread data are constructed from 10-year government bond rates and 3-month treasury rates or closest equivalents. The appendix details the construction of these time series.

3.2 Within-sample Regression

We start with a simple bivariate model:

$$IPGrowth_{t,t+k} = \beta_0 + \beta_1 Spread_t + \varepsilon_{t+k} \quad (2)$$

Where $IPGrowth_{t,t+k}$ is the annualized growth rate over the period t through $t+k$, and $Spread_t \equiv i_t^{10yr} - i_t^{3mo}$, the 10-year government bond rate minus the 3-month treasury yield (or closest equivalent).

In words, the yield spread at time t predicts the annualized growth rate of industrial production for the time span beginning in period t to $t+k$ months ahead. We examine this model with k equal to 12 and 24 (i.e. growth over a one and two year time horizon). Since adjacent year over year growth figures will be drawing from overlapping data points, the resulting error terms will be serially correlated. To account for this serial correlation, we conduct our statistical inferences using heteroscedasticity and serial correlation robust standard errors⁶.

We turn first to the results from the model using the complete data set (1970-2013), displayed in Table 1⁷. The coefficient estimates on the yield spread is positive and significant

⁵For instance, the correlation between GDP and IP growth in the US and UK are .76 and .72 respectively.

⁶Unit root tests indicate that the spreads and industrial production changes are stationary.

⁷Appendix table A.1 compares results using industrial production to results using GDP. Results are qualitatively similar. Empirically, industrial production has a higher variance, which explains the larger

for all countries suggesting the yield spread may hold forecasting value. The magnitude of the parameter estimate is also of economically important. Consider the coefficient estimate of 1.22 for France; this point estimate implies that for each percentage point increase in the yield spread, French industrial production growth over the next year will increase by and additional 1.22 percentage points. Estimates across countries in our data set vary markedly, ranging from a high of 1.81 in Canada to a low of 0.69 in the United Kingdom.

Despite the existence of statistically significant coefficient estimates for each country, the goodness of fit (according to the R-squared statistic) varies substantially across country models. That being said, the *relative* proportion of variation across countries is of interest. The yield spread in United States, Germany, and Canada explains more than 20 percent of the changes in annual industrial production growth. In contrast, the yield spread explains less than 10 percent of the variation for Italy, Japan, and Sweden. The Durbin-Watson statistics indicate a high degree of serial correlation. In addition, the White statistics signal heteroskedasticity in most, but not all, instances. The use of Newey-West robust standard errors account for these characteristics of the estimated residuals⁸.

Following Bonser-Neal and Morley (1997) and Kozicki (1997), we examine the corresponding specification for growth over a two year horizon, displayed in the lower panel of Table 1. While many of the variables are still significant, the explanatory power of the model deteriorates for many countries. Additionally, in every case the magnitude of the yield spread coefficient is smaller in the two-year model relative to the one-year model. The decrease in explanatory power and magnitude of the coefficient estimates at the two-year versus one-year horizon suggests most of the explanatory power is concentrated at the former horizon⁹. Only the German, United Kingdom and United States models exhibit better fit in the two-year model relative to the one-year model.

coefficient estimates. The estimates using industrial production are actually more precise than when using GDP.

⁸Successive 12-month growth observations share 11 overlapping months of data by construction, therefore we choose a lag length of 11 for the Newey-West standard errors.

⁹For an empirical investigation into this issue see Kozicki (1997).

In order to investigate the time variation in the strength and nature of the yield curve/growth relationship, we split the sample at 1997/98. The choice is primarily pragmatic in nature; it sets each subsample to be roughly similar in size. At the same time, the choice is somewhat fortuitous, as the latter subsample then conforms approximately to the post-EMU period.

Tables 2 and 3 contain results from the two sub-samples of data, and highlight a key finding. The strength of the relationship between term spreads and output growth is driven by the early portion of the sample. Regressions from the early sample (1970-1997) produce precise coefficients estimates in eight of nine countries. In contrast, when using more recent data (1998-2013) estimates are less precise but much larger in magnitude making it difficult to determine if the relationship between the yield spread and growth has deteriorated or intensified.

Examining the R-squared across sub-samples: four of the models exhibit a better fit when using the later data subset. Japan exhibits the sharpest drop-off in model fit across time periods, the yield spread explains nearly 20 percent of the variation in industrial production growth in the 1970-1997 subsample and explains almost nothing in the 1998-2008 subsample. The later period coincides with the Asian financial crisis and may reflect Japan's short term rates hitting the zero lower bound. One implication of the Japanese results, relevant to current debate, is that we might anticipate a deteriorated fit for the US yield curve/output relationship, given the effective Fed Funds rate has essentially hit zero.

3.3 Out-of-sample Forecasting

A common criticism of using in-sample fit to assess model validity is that it fails to confront the model with the real-world challenge of forecasting with limited data. Specifically, coefficient estimates from Table 1 were generated using the entire dataset from 1970-2013. Someone trying to forecast next year's industrial production growth in 2000 wouldn't have been able to use data from 2000-2013 to generate a forecast, they would have only had access to data up to 2000. Using the coefficients in Table 1 to forecast could overstate the predictive

power of the independent variable.

In this section we conduct pseudo-out-of-sample forecasts. Instead of using the entire dataset to generate coefficient estimates for forecasting, we run recursive regressions. Hence, each regression contains only information that predates the time period we are forecasting. For example, to forecast industrial production growth from January 1980 through 1981 we regress industrial production on yield spreads using only data that would have been available prior to January 1980 (i.e. Jan. 1970- Dec. 1979). Coefficients from this regression are used to forecast industrial production growth from January 1980 - 1981. Then, to estimate growth from February 1980 to February 1981, we re-run the regressions using data from January 1970 - January 1980, obtain new parameter estimates used to forecast, and so on.

This process generates a series of predicted industrial production growth, each prediction forecasted from a unique regression. To evaluate the performance of this forecasting model we compare the root mean square error (RMSE) relative to historical data against a naïve forecast RMSE. Our naïve forecast is a simple AR1 model of growth. We also calculate the RMSE for a forecast using three other specifications: AR(1) and the yield spread, the yield spread and 3 month rate, and the yield spread, 3-month rate and AR(1). We conclude that there exists a marginal benefit to estimating a growth model with the yield spread (as opposed to the simple AR(1) model) if the RMSE from the yield spread model specification is significantly less than that of the AR(1) model (according to the Diebold-Mariano statistic). Figure 2 displays the fitted values for Euro area countries of the the out-of-sample model, using the yield spread as the independent variable and using the AR(1) model. While extreme fluctuations were not always well predicted, the general shape of the data seems to be captured in many cases, certainly when compared to the AR(1) model. Notably, the yield spread did not generate predicted contractions in the late 2000s but tracked the actual series fairly well in Canada and the US during the subsequent recovery.

Results relative to the AR(1) model across all countries are mixed. Table 4 displays the results of the RMSE scores for all model specifications. The yield curve model (column 2)

exhibits lower RMSE than the AR(1) model (column 1) for all countries except Japan and the US. However we only reject the test for equal forecasting power for Germany according to the Diebold-Mariano test. When we include the 3-month interest rate (column 4) forecasts for Canada and the United States are significantly better than the AR(1).

The relatively poor out-of-sample results could, in part, be due to fundamental changes in the relationship between the yield curve and economic activity over time. If the structure of the relationship changed in the middle of our sample, coefficient estimates using historical data may not be useful in predicting future growth out-of-sample. A number of events over the past ten years may have affected the predictive power of the yield curve including: the advent of the European monetary union, the “great moderation”, the global savings glut and the Japanese experience with a ZLB policy rate.

3.4 Rolling Window Regressions

To examine changes in the predictive power of the yield curve over time we use rolling window regressions. For each country we restrict data to include only January of 1970 through December of 1979 and regress growth on the yield spread to obtain a coefficient estimate. Then we run another regression using data from February of 1970 through January of 1980, and so on. Figure 4 plots the coefficient estimates on the yield curve from these regressions and 95% confidence intervals for each overlapping 10 year interval beginning with January 1970 – December 1979 through January 2013 –December 2013. Generally declining coefficient estimates and widening confidence bands confirm our suspicion that the relationship between the yield curve and economic growth has deteriorated over the last ten to fifteen years. However many models exhibit a significant strengthening during the Great Recession.

The Euro area countries appear similar to one another in some respects: the coefficient estimates tend to decline into 1990 when they generally become insignificant. This is consistent with the fact that many macroeconomic variables (including both industrial production

and the yield spread) became significantly less volatile decreasing the detectability of any relationship. The recent uptick in the coefficient estimates is consistent with recent macroeconomic volatility.

Canada, the United Kingdom and the United States all exhibit deterioration post-1998; the significance band widens in the United States and Canada while the coefficient estimate draws closer to zero in the United Kingdom. Some have speculated that the global savings glut may have affected not only the United States but also other countries with strong legal regimes and liquid financial markets¹⁰. If Canada and the United Kingdom were affected by the global savings glut in the same way that the United States may have been, this is the coincidental deterioration one might expect. Certainly there exist other potential confounding factors, yet it remains an interesting coincidence.

4 The Yield Curve and Recessions

We now move to a nonlinear version of the same question we asked earlier, to the extent that recessions are a specific characterization of (negative) output growth. Following Montea (2003) and Wright (2006), we test if the yield spread is a predictor of recessions, defined as a binary dependent variable.

There is little agreement in terms of the findings in the literature, especially in this cross-country context. While Montea (2003) finds the yield curve alone is a useful predictor of recessions when using aggregate Euro-area data, Wright (2006) argues there is no reason to believe that an increase in the short-term interest rate should have the same consequence as a decrease in the long term rate. Consequently, Wright (2006) augments the conventional recession/yield curve specification with the Federal funds rate to isolate the effect of changes in the short-term rate. Indeed, Wright's model performed better when adding the federal funds when using United States data. Following the literature, the models we use are as follows:

¹⁰See, for example, the 2009 Economic Report of the President, Chapter 2.

$$\Pr(R_{t+1,t+k} = 1) = \phi(\beta_0 + \beta_1 Spread_t)$$

$$\Pr(R_{t+1,t+k} = 1) = \phi(\beta_0 + \beta_1 Spread_t + \beta_2 3mo_t)$$

Where t is the current time period and k is the forecast period and $\phi(\dots)$ denotes the standard normal cumulative distribution function. We use the 3-month interest rate to isolate the effect of movements in short-term interest rates. The recession indicator variable equals one if there is a recession in any month between $t + 1$ through $t + k$, inclusive. We estimate both models using k equal to 6 and again with k equal to 12 (i.e. a six month and one year forecast).

Tables 5 and 6 display the results from the probit model estimates for each country over the full sample. The top block of each table reports results from a six-month forecasting horizon, while the lower block displays the twelve-month forecasting results. For the United States, our results differ somewhat from the results obtained by Wright (2006); the yield spread parameter is significant over both the six-month and twelve-month forecasting periods even when the short term rate is included in the regression. However, the 3-month interest rate parameter is statistically insignificant over either horizon.

Results from the Germany and Canada models are similar to the United States model: the yield spread is significant even with the addition of the short-term interest rate and the short-term interest rate parameter is not statistically significant at either forecast horizon. Interestingly, results for the some of the remaining countries are starkly different. Across many other non-US countries, adding the short term rate to the model reduces both the magnitude and significance of the yield spread. In Sweden the short-term rate is significant while the yield spread coefficient actually becomes statistically insignificant. For Japan, adding the short term yield makes the coefficient on the yield spread significant. In all countries excluding Japan, the coefficient on for the short-term interest rate is positive, suggesting high relative short-term interest rates precede periods of slower growth.

We display in Figure 5 the estimated probabilities of recession in the subsequent 12 months using only the yield spread as an explanatory variable. Generally speaking reces-

sions were well predicted by the yield curve across countries in the 1970s and 1980s. When we look at recessions in the 1990s and 2000s however, results are less consistent. United States and German recession probabilities peaked near one hundred percent predicted probability prior to the recessions in the 1970s and 1980s, as anticipated. Additionally the estimated probability exceeded 80 percent preceding the 1990 recession. While the probability peaked at lower levels before the 2000 and 2007 recessions, in both cases the model ascribed a probability well in excess of 50 percent. The results for the England, Sweden, France and Canada paint a different picture. Probabilities generated by the model fit the recession data reasonably well through 1990; however, models were largely unresponsive in the months leading up to the 2007 recession. These findings suggest something may have been structurally different about the recessions of the 2000s. Results in Japan and Italy are generally quite poor. When using only the yield spread as in independent variable the coefficient is not statistically significant and the model explains almost nothing.

5 Real-time Data

In the previous exercises we used historical data as they are currently reported. However industrial production data, as are most measures of economic activity, is subject to revision. For instance, United States industrial production for December 2008 was originally reported as 106.1 by April 2009, December data had been revised down to 104.8. From a forecasting perspective, using data as it appears most recently (the current vintage) is not the same as using data as it looked prior to the estimation period. If, today, we want to evaluate how the model would have performed in December 2008, using data as it appeared in December 2008 more closely simulates estimating the model in 2008.

Koenig, Dolmas & Piger (2003) point out that the relationship between early estimates of economic output and early estimates of explanatory variables is the relationship of interest to forecasters. To capture the relationship between early estimates of output and explanatory

variable Koenig, Dolmas and Piger (2003) suggest creating a “real-time vintage” by compiling a single time series for each variable that include only the first estimate. Furthermore, Koenig, Dolmas and Piger argue that revisions to data are unpredictable (essentially extraneous noise) at the time of issuance so using a real-time vintage on the left-hand side of an equation eliminates the noise and in fact provides more accurate forecasts.

In this section we use real-time vintage data created from the OECD Main Economic Indicators real-time data and revisions database¹¹. Due to data availability, we use real GDP as a measure of economic output and restrict our sample of countries to: Canada, Germany, Japan, U.K. and U.S. Since the interest rates used to construct the yield spread are not typically revised, using the current vintage for the yield spread sufficiently represents a real-time vintage. The dataset contains GDP vintages from 1987Q3 to 2013Q2. To construct this dataset we have a series of real GDP vintages for Canada, Germany, Japan, U.K. and the U.S. For each vintage we calculate four-quarter GDP growth. We collapse the set of GDP vintages down to one series for each country that contains only the final observation from each vintage (the initial data release). Current-vintage yield spread data is used to predict four-quarter GDP growth rates in the constructed ‘real-time vintage’.

Table 11 displays the results of the real-time data analysis. Significant parameter estimates across all countries (for the US only at the 90 percent confidence level), except Japan, suggest the yield curve does tend to provide significant information regarding first estimate economic growth over the next four quarters. Table 12 shows a comparable set of regressions where the current vintage of GDP is used to calculate growth rates. Results using current-vintage data are very similar to the real-time data results. Industrial production data tend to be revised to a smaller degree than GDP, therefore finding similar results across current-vintage and real-time datasets suggest one can be more confident that the findings in the previous sections using only current-vintage data are not driven by the current-vintage structure.

¹¹Vintages prior to 2004 were graciously provided by Lucio Sarno, as used in Sarno and Valente (2009)

6 Conclusion

This paper has explored the importance of the yield spread in forecasting future growth and recession. Generally speaking, when using the entire data series from 1970-2013, in-sample results suggest the yield spread is indeed important and has significant predictive power over a one-year time horizon. The results deteriorate when forecasting growth two years ahead. Moreover, it appears that the forecasting power is weaker during the great moderation up until the financial crisis of 2008. However, each of the six European country models exhibited relatively high R-squared statistics (above 0.1) when using data from 1998-2013. While the explanatory power is somewhat less for certain models estimated over the early subsample, the data still suggest the yield curve possesses some forecasting power for European countries.

The results we obtained in the out-of-sample forecasting exercises were somewhat less definitive. Of the European countries examined, only for Germany did the yield curve possess significantly greater predictive power than a simple AR(1). Certainly the relationship between the yield spread and growth has declined in recent years; however it appears that the relationship has held up best in some European countries and may have strengthened with the increasing volatility of macroeconomic data over the past few years.

The contrast across countries was marked when predicting recessions. The short-term rate was significant in several instances; however its inclusion often resulted in a decrease in the economic and statistical significance of the yield spread. The model predicted recessions relatively well for the US, Germany and Canada over the entire data set while the remaining models largely failed to anticipate the recessions of the 2000s. The Japan and Italy models did not predict recessions well.

In summary, we do not obtain a simple story for the yield curve's predictive power. The yield curve clearly possesses some forecasting power. However, there is also some evidence the United States is something of an outlier, in terms of its usefulness for this purpose. And overall, the predictive power of the yield curve seems to have rebounded in the lead up to the Great Recession, reversing a longer term trend of declining predictive power.

Notes: Data from column is restricted to the country in the column header. Italy and Sweden samples begin in Jan. 1971, Netherlands sample begins in Oct. 1972.

The yield spread is the 10-year government bond yield minus the 3-month treasury yield (or closest equivalent).

Durbin-Watson is the d-statistic to test for first-order serial correlation.

White is the p-value from White's test of heteroskedasticity.

HAC standard errors in brackets (** P<.05, *** P<.01).

Notes: Data from column is restricted to the country in the column header. Italy and Sweden samples begin in Jan. 1971, Netherlands sample begins in Oct. 1972.

The yield spread is the 10-year government bond yield minus the 3-month treasury yield (or closest equivalent). HAC standard errors in brackets (** P<.05, *** P<.01). Reported R-squared is pseudo R-squared.

Appendix

Data for this paper came from two sources. All of the recent data came from Haver Analytics. When the series in Haver did not extend back to 1970, the Haver series were spliced with data from the Bonser-Neal and Morely (1997) dataset. These data include the following:

Canada:

3-month interest rate from 1/1970 to 12/1979 (IFS)

Industrial Production from 1/1970 to 12/1980 (BIS)

France:

3-month interest rate from 1/1970 to 5/1989 (BIS)

10-year interest rate from 1/1970 to 8/81 (BIS)

Germany:

10-year interest rate from 1/1970 to 12/1979 (OECD, FRB)

Italy:

3-month interest rate from 1/1971 to 12/1979 (IFS)

10-year interest rate from 1/1970 to 12/1979 (BIS, IFS)

Industrial Production from 1/1960 to 12/1979 (BIS)

Japan:

3-month interest rate from 1/1970-4/1979 (BIS)

10-year interest rate from 1/1970 – 8/1987 (BIS)

Netherlands:

3-month interest rate from 10/1972 – 12/1981 (BIS)

10-year interest rate from 1/1970-4/1982 (IFS)

Industrial Production from 1/70 – 12/79 (IFS)

Sweden:

3-month interest rate from 1/1970 – 12/1982 (IFS)

10-year interest rate from 1/1970 – 12/1986 (IFS)

Industrial Production from 1/1970 – 12/1989 (FRB)

UK:

3-month interest rate from 1/1970-12/1985 (FRB)

Table A.1: Current Yield Spread as Predictor of Future Growth: GDP vs IP
