REGRESSION-BASED TESTS OF PREDICTIVE ABILITY*

BY KENNETH D. WEST AND MICHAEL W. MCCrackEN††

University of Wisconsin, U.S.A.
Louisiana State University, U.S.A.

We develop regression-based tests of hypotheses about out of sample prediction errors. Representative tests include ones for zero mean and zero correlation between a prediction error and a vector of predictors. The relevant environments are ones in which predictions depend on estimated parameters. We show that standard regression statistics generally fail to account for errors introduced by estimation of these parameters. We propose computationally convenient test statistics that properly account for such errors. Simulations indicate that the procedures can work well in samples of size typically available, although there sometimes are substantial size distortions.

1. INTRODUCTION

In this paper, we develop and simulate regression tests for properties of out of sample prediction errors. Examples of such properties are: zero mean, zero serial correlation (if the prediction is one-step ahead), zero correlation with the prediction, and zero correlation with the prediction from another, non-nested model. Empirical papers that examine these or related properties include Mincer and Zarnowitz (1969), Nelson (1972), Howrey et al. (1974), Berger and Krane (1985), Meese and Rogoff (1983, 1988), Akgiray (1989), Diebold and Nason (1990), Fair and Shiller (1990), Pagan and Schwert (1990), West and Cho (1995) and some of the participants in the Makridakis et al. (1982) competition.

If the predictions do not depend on estimated parameters, it follows from Diebold and Mariano (1995) that under mild conditions standard regression statistics may be used. For zero serial correlation in one step ahead prediction errors, for example, one can simply regress the period $t + 1$ prediction error on the period $t$ prediction error, and use a standard $t$-test to test the null that the coefficient is zero.

But if the predictions do depend on estimated parameters, the results of Diebold and Mariano (1995) need not apply. The usual tests do account for uncertainty that

†† We thank Frank Diebold, Neil Ericson, Art Goldberger, Matthew Higgenes, Yuichi Kitamura, three anonymous referees and seminar participants at the 1996 Midwest Economics Association Meetings, the Federal Reserve Board of Governors U.S.A., the University of Maryland, the Chinese University of Hong Kong, the Federal Reserve Bank of Kansas City and the University of Wisconsin, U.S.A., for helpful comments, and the National Science Foundation and the Graduate School of the University of Wisconsin, U.S.A., for financial support.
would be present if (counterfactually) the underlying parameter vector were known rather than estimated, but ignore uncertainty resulting from error in estimation of that parameter vector. Using a conventional set of assumptions, we establish conditions under which this second type of uncertainty is asymptotically negligible, thereby validating the Diebold and Mariano (1995) procedure. More importantly, we show that such uncertainty sometimes is asymptotically nonnegligible, and then suggest computationally convenient ways to obtain test statistics that account for both types of uncertainty. Simulations indicate that failure to account for the second type of uncertainty sometimes results in poorly sized hypothesis tests, while our own adjusted tests usually but not always yield more accurately sized tests.

A vast literature has considered predictive accuracy. A distinguishing element of our work is explicit consideration of the role of estimation of parameters needed for prediction. We focus on test statistics produced by regression packages. These have appeared in a number of applied papers (e.g., Fair and Shiller 1990, and Pagan and Schwert 1990), and, we hope, may appear in still more papers upon development of techniques such as those proposed here.\(^1\) We build on earlier work (especially West 1996) not only by developing computationally convenient procedures, but also by allowing additional sampling schemes (additional ways of dividing available data into estimation and prediction components), relaxing certain technical conditions that implicitly ruled out certain important tests (including zero correlation between a prediction error and a prediction), and supplying new simulation evidence.

Section 2 of the paper describes the environment. Sections 3 and 4 present technical assumptions and basic asymptotic results. Section 5 presents our computationally convenient adjustments to standard regression statistics. Sections 6 and 7 specialize on the discussions in Sections 3–5 to consider some common tests, when the underlying models are linear and exactly identified. Section 8 presents simulation evidence and concludes. The Appendix presents proofs. An additional Appendix available on request from the authors presents details of proofs and simulation results omitted from the paper to save space.

2. DESCRIPTION OF ENVIRONMENT

Let \( \tau \geq 1 \) be the prediction horizon of interest. There are \( P \) predictions in all, which rely on estimates of a \( (k \times 1) \) unknown parameter vector \( \beta^* \). To avoid certain singularities we assume \( k > 0 \) and merely note that our results specialize in the obvious way when regression estimates are not required to make predictions.

The first prediction uses data from period \( R \) or earlier to predict a period \( R + \tau \) event, the second from period \( R + 1 \) or earlier to predict a period \( R + 1 + \tau \) event, \( \ldots \), the last from period \( R + P - 1 = T \) or earlier to predict a period \( T + \tau \)

\(^1\) We hope our work will be useful even for the interpretation of completed papers. With the exception of one paper that came to our attention after this paper was written (Hoffman and Pagan 1989), to our knowledge all such papers have used standard regression statistics, without adjusting for dependence of predictions on estimated parameters. We establish conditions for the asymptotic validity of such statistics, and in some cases we are able to propose adjustments for such dependence that can be made even without access to the data. See Sections 4, 5 and 7.
event. The total sample size is \( R + P - 1 + \tau = T + \tau \):

\[
R \quad R + \tau \quad R + P - 1 = T \quad T + \tau
\]

Observation: 1

In estimating \( \beta^* \), three different schemes to use available data are prominent in the forecasting literature. We consider the three explicitly because results vary for the three. The first scheme, which we call recursive, was used by, for example, Fair and Shiller (1990). This scheme uses all available data, estimating \( \beta^* \) first with data from 1 to \( R \), next with data from 1 to \( R + 1, \ldots \), and finally with data from 1 to \( T \). The second scheme, which we call rolling, was used by, for example, Akgiray (1989). This scheme fixes the sample size, say at \( R \), and drops distant observations as recent ones are added. Thus, \( \beta^* \) is estimated first with data from 1 to \( R \), next with data from 2 to \( R + 1, \ldots \), and finally with data from \( P \) to \( T \). The third and final scheme, which we call fixed, was used by, for example, Pagan and Schwert (1990). This scheme estimates \( \beta^* \) just once, say on data from 1 to \( R \), and uses the estimate in forming all \( P \) predictions; data realized subsequent to \( R \) are, however, used in forming predictions, as described in the previous paragraph and below.

For \( t = R, \ldots, T \), let \( \hat{\beta}_t \) be the regression vector used for prediction when data from period \( t \) and earlier are used. In the least squares model \( y_t = X_t' \beta^* + u_t \), for example, \( \hat{\beta}_t \) is estimated using

\[
(2.1) \quad \text{data from 1 to } t \text{ in the recursive scheme,}
\]

\[
\hat{\beta}_t = \left( \sum_{s=1}^{t} X_s X_s' \right)^{-1} \sum_{s=1}^{t} X_s y_s,
\]

\[
\text{data from } t - R + 1 \text{ to } t \text{ in the rolling scheme,}
\]

\[
\hat{\beta}_t = \left( \sum_{s=t-R+1}^{t} X_s X_s' \right)^{-1} \sum_{s=t-R+1}^{t} X_s y_s,
\]

\[
\text{data from 1 to } R \text{ in the fixed scheme,}
\]

\[
\hat{\beta}_t = \left( \sum_{s=1}^{R} X_s X_s' \right)^{-1} \sum_{s=1}^{R} X_s y_s.
\]

Note that for the fixed scheme, \( \hat{\beta}_t \) is the same for all \( t \), and depends only on \( R \) and not \( t \), while in the recursive and rolling schemes a different regression estimate is used for each \( t \). In addition, for the rolling and fixed schemes, \( \hat{\beta}_t \) should properly be subscripted \( \hat{\beta}_{t,R} \); the dependence on \( R \) is suppressed for notational simplicity. The asymptotic approximation assumes that both \( P \) and \( R \) are large (formally, \( P, R \to \infty \)), with \( \tau \) fixed.

One is interested in the relationship between a scalar prediction error and a vector of variables—say, whether the prediction error is correlated with the vector of variables. As illustrated in example 2 below, we can limit the formal discussion to prediction errors and still yield results applicable to inference about predictions as
well; given the linearity of the procedures we analyze, results for predictions (= observed data point – prediction error) follow immediately. We limit the formal analysis to a scalar dependent variable to economize on notation; we comment occasionally on vector generalizations of our results.

Let $v_{t+\tau}(\beta^*) = v_{t+\tau}$ be the scalar prediction error of interest, with $v_{t+\tau}(\hat{\beta}_t) = \hat{\beta}_{t+\tau}(\hat{\beta}_{t+1})$ the corresponding random variable evaluated at $\hat{\beta}_t$. As the dating suggests, $v_{t+\tau}$ typically relies on data realized in period $t + \tau$. One is interested in the linear relationship between $v_{t+\tau}$ and a vector function of period $t$ data. Let $g_{t+\tau}(\beta^*) = g_{t+\tau}$ denote this $(l \times 1)$ vector function, with $g_{t+\tau}(\hat{\beta}_t) = \hat{g}_{t+\tau}$ the sample counterpart evaluated at $\hat{\beta}_t$. In most applications $l$ is small, say $l = 1$ or $l = 2$. Here, $g_{t+\tau}(\beta^*)$ depends on data observed in period $t$ and earlier; the dating convention is used because $g_{t+1}$ often depends on the predetermined variables available at time $t + 1$. See the examples below.

The aim is to use a least squares regression to test the null hypothesis that $E v_{t+\tau} g_{t+\tau} = 0$. The obvious regression is one of $\hat{v}_{t,t+\tau}$ on $\hat{g}_{t+\tau}$ for $t = R, \ldots, R + P - 1$, obtaining

$$
(2.2) \quad \hat{v}_{t,t+\tau} = \hat{g}_{t+\tau} \hat{\alpha} + \hat{\eta}_{t+\tau}, \quad \hat{\alpha} = \left( \sum_{t=R}^{T} \hat{g}_{t+\tau} \hat{g}_{t+\tau} \right)^{-1} \sum_{t=R}^{T} \hat{g}_{t+\tau} \hat{v}_{t,t+\tau}, \quad \hat{\eta}_{t+\tau} = \hat{v}_{t,t+\tau} - \hat{g}_{t+\tau} \hat{\alpha}.
$$

One then uses the estimate of $\hat{\alpha}$ and a suitable variance-covariance matrix to test the null.

To illustrate, here are four examples, illustrated with the simple zero mean AR(1) model $y_t = \beta^* y_{t-1} + u_t$, $|\beta^*| < 1$.

1. **Mean Prediction Error.** Here, $g_{t+1} = 1$ is a scalar. If $v_{t+\tau}$ is a $\tau$ step ahead forecast error in the AR(1) model, then $\hat{v}_{t,t+\tau}$ is $y_{t+\tau} - \hat{\beta}_t y_t$.

2. **Efficiency.** Here, one regresses $y_{t+\tau}$ on the period $t$ prediction (= $\hat{\beta}_t y_t$, in the AR(1) model) and perhaps a constant and other possible predictors as well. The null is that the coefficient on the prediction is unity, and on any other included variables is zero. To analyze this regression using our framework, which presumes that the dependent variable is a prediction error, note that if one uses the prediction error ($y_{t+\tau} - \hat{\beta}_t y_t$ in the AR(1) model) as the dependent variable the regression results are algebraically identical to those with $y_{t+\tau}$ on the left-hand side, except that the estimated coefficient on the prediction will be smaller by unity. Hence, for say $\tau = 1$, if $\hat{g}_{t+1}$ is $(2 \times 1)$ and includes a constant term as well as $\hat{\beta}_t y_t$, $H_0$ is $\alpha = (0, 0)'$. Note the dating convention: $\hat{g}$ is dated $t + 1$, but depends on $y_t$, the regressor available for prediction at time $t + 1$.

3. **Encompassing.** Here, $v_{t+1}$ is a one step ahead forecast error from a putatively encompassing model. The right-hand side variable $\hat{g}_{t+1}$ is the scalar prediction from a putatively encompassed model, and the null is $\alpha = 0$. More generally, the
right-hand side might include a constant, in which case \( \hat{g}_{t+1} \) and \( \alpha \) are \( (2 \times 1) \) and the null is \( \alpha = (0, 0)' \).

4. Serial Correlation. If \( u_{t+1} \) is the one step ahead forecast error in a model presumed to have serially uncorrelated errors ( \( = u_{t+1} \) in the AR(1) model), then \( g_{t+1} = u_{t} \) is the previous period's forecast error. So \( \alpha \) is a scalar, \( \hat{\alpha} \) an estimate of the first-order serial correlation coefficient, and \( H_0 \) is \( \alpha = 0 \). \(^{3}\)

One of our major aims is to develop computationally convenient procedures, which in our regression context means using standard errors produced by standard computer programs, or perhaps simple adjustments to those standard errors. As we shall see, conventional test statistics are not always asymptotically valid, even when \( \tau = 1 \) and \( u_{t+1} = u_{t+1}^\beta \) is a zero mean i.i.d. variable that is independent of \( g_{t+1} = g_{t+1}^\beta \). The reason is that in some applications, two sources of uncertainty affect asymptotic inference about \( \alpha \). The first is uncertainty that would be present even if (counterfactually) \( \beta^* \) were known and one could regress \( u_{t+\tau} \) on \( g_{t+1} \). The second results from use of \( \hat{\beta}_t \) rather than the unknown \( \beta^* \). According to our asymptotic approximation, standard regression statistics properly account for the first source of uncertainty but not necessarily the second. We show below that in some important examples, properly accounting for both sorts of uncertainty requires merely rescaling the least squares variance-covariance matrix by a certain function of \( \sqrt{P/R} \).

When such a simple adjustment does not suffice, one can sometimes obtain asymptotically valid test statistics by augmenting the regression (2.2) with a judiciously chosen set of variables \( \hat{g}_{2t+1} \). In this case, one runs the regression

\[
\hat{u}_{t,t+\tau} = \hat{g}_{t+1}' \alpha + \hat{g}_{2t+1} \alpha_2 + \text{disturbance} = \hat{g}_{t+1}' \tilde{\alpha} + \text{disturbance},
\]

where \( \hat{g}_{2t+1} \) is a \( (r \times 1) \) set of extra variables included so that conventionally computed hypothesis tests on \( \alpha \) are correctly sized according to our asymptotic theory; \( \hat{g} = (\hat{g}_{t+1}', \hat{g}_{2t+1}') \) is \( (l + r) \times 1 \); \( \hat{g}_{t+1} = \hat{g}_{t+1}^\beta \equiv (g_{t+1}^\beta)' \equiv (g_{t+1}, (\beta^*)')' \equiv (g_{t+1}', g_{2t+1}') \) and \( \tilde{\alpha} \) are also \( (l + r) \times 1 \).

3. ASSUMPTIONS

This section presents assumptions relevant for the basic regression (2.2); Section 5 will present an extension for analysis of the augmented regression (2.3). Our assumptions are ‘high level’ ones. We use relatively abstract assumptions for two reasons. First, they allow us or others to verify that our results apply to tests and models other than the ones we consider in detail in Sections 6 and 7 below. Second, this test is most naturally run by regressing \( y_{t+1} - \hat{\beta}_t y_t \) on \( y_t - \hat{\beta}_{t-1} y_{t-1} \). Strictly speaking, our notation implies that \( y_{t+1} - \hat{\beta}_t y_t \) rather than \( y_{t+1} - \hat{\beta}_t y_t \) is on the left; we assume that both left- and right-hand side variables are constructed from the same estimate of \( \beta^* \), and a rank condition presented below rules out simply defining parameters so that the population parameter of interest is \( 2 \times 1 \) without a \( 2 \times 1 \) period \( t \) estimate of \((\hat{\beta}_t, \hat{\beta}_{t-1})'\). But this rank condition is easily relaxed, and results may be generalized to allow the natural version of this test. To economize on notation, we do not explicitly do so in this paper.
they can be presented compactly. In the interest of concision and clarity, we also do not attempt to state each theorem using a minimal set of assumptions. For example, a weaker version of Assumption 3 applies in applications with parametric covariance matrix estimators.

Some notation: for any differentiable function \( n_i : \mathbb{R}^m \to \mathbb{R}^l \) and for \( x \) in the domain of \( n_i \), \( \partial n_i / \partial x \) denotes the \((s \times m)\) matrix of partial derivatives of \( n_i \); for any function \( n_i \) whose domain is in \( \mathbb{R}^k \), \( n_i(\beta^*) = \partial n_i(\beta^*) / \partial \beta \); for any matrix \( A = [a_{ij}] \), let \( |A| = \max_{i,j} |a_{ij}| \); summations of variables indexed by \( t \) or \( t + \tau \) run from \( t = R \) to \( t = R + P - 1 \); for any variable \( x \), \( x(t) = \sum_{t = r}^{T} x(t) \); \( x_{t+\tau} = \sum_{t = R}^{T} x_{t+\tau} \); summations of variables indexed by \( s \) run from \( s = 1 \) to \( s \); for any variable \( x \), (a) \( \sum x_s = \sum_{s = 1}^T x_s \) (recursive), (b) \( \sum x_s = \sum_{s = 1}^T x_s \) (rolling), or (c) \( \sum x_s = \sum_{s = 1}^T x_s \) (fixed). Finally, let

\[
(3.1) \quad f_{t+\tau}(\beta^*) = g_{t+\tau}(\beta^*) v_{t+\tau}(\beta^*), \quad f_{t+\tau, \beta} = \frac{\partial f_{t+\tau}(\beta^*)}{\partial \beta}, \quad F = Ef_{t+\tau, \beta}.
\]

Here, \( f_{t+\tau} : \mathbb{R}^k \to \mathbb{R}^l \); the \((l \times k)\) matrix \( F \) is not subscripted by \( t \) in accordance with a stationarity assumption about to be made.

**Assumption 1.** (a) In some neighborhood \( N \) around \( \beta^* \), and with probability 1, \( v_i(\beta) \) and \( g_i(\beta) \) are measurable and twice continuously differentiable; (b) \( E v_{t+\tau} g_{t+1} = 0 \); (c) \( E v_i v_i = 0 \); (d) \( E v_i g_{t+1} = 0 \); (e) \( E g_i g_i' \) is of rank \( l \).

**Assumption 2.** The estimate \( \hat{\beta} \), satisfies \( \hat{\beta} - \beta^* = B(t) H(t) \), where \( B(t) \) is \((k \times q)\) and \( H(t) \) is \((q \times 1)\), with (a) \( B(t) \to_{a.s.} B \), \( B \) a matrix of rank \( k \); (b) \( H(t) = \sum_{s \geq 0} h_s(\beta^*) \) (recursive) or \( H(t) = \sum_{s \geq 0} h_s(\beta^*) \) (rolling or fixed) for a \((q \times 1)\) orthogonality condition \( h_s(\beta^*) \); (c) \( \lim_{t \to \infty} \mathbb{E} h_t(\beta^*) = 0 \); (d) in the neighborhood \( N \) of assumption 1, \( h_t \) is measurable and continuously differentiable.

**Assumption 3.** In the neighborhood \( N \) of Assumption 1, there is a constant \( D < \infty \) such that for all \( t, \sup_{\beta \in N} |\partial^2 \nu_i(\beta) / \partial \beta \beta^*| < m_t \) for a measurable \( m_t \) for which \( Em_t < D \). The same holds when \( \nu_i \) is replaced by an arbitrary element of \( g_i \).

**Assumption 4.** Let \( \nu_i = (\nu_i^r, \nu_i^g, \nu_i^h, \nu_i^g)' \). (a) For some \( d > 1 \), \( \sup_{\beta \in N} E \| w_i \|_d < \infty \), where \( \| \cdot \| \) denotes Euclidean norm. (b) \( w_i \) is strong mixing, with mixing coefficients of size \(-3d/(d-1)\). (c) \( w_t \) is fourth-order stationary. (d) Let \( \Gamma_{jj}(j) = Ef_{j} f_{j-\tau}, S_{jj} = \sum_{j = -\infty}^{\infty} \Gamma_{jj}(j) \). Then \( S_{jj} \) is positive definite.

**Assumption 5.** \( R, P \to \infty \) as \( T \to \infty \), and \( \lim_{T \to \infty} P/R = \pi \), (a) \( 0 \leq \pi \leq \infty \) for recursive \( \pi = \infty \iff \lim_{T \to \infty} R/P = 0 \); (b) \( 0 \leq \pi < \infty \) for rolling and fixed.

Note that from Assumptions 1(b) and 1(d),

\[
(3.2) \quad Ef = 0, \quad F = Ef g_{t+1} \left( \frac{\partial v_{t+\tau}}{\partial \beta} \right).
\]
In allowing not only for recursive but also rolling and fixed sampling schemes, Assumptions 2–5 generalize similar assumptions in West (1996), where some discussion of the assumptions may be found. To illustrate briefly here: The moment conditions in Assumptions 3 and 4 rule out unit autoregressive roots, but otherwise do not seem restrictive. Assumption 2 allows standard estimation techniques, including GMM and maximum likelihood. In the AR(1) model of Section 2, for example, $B = (E y_{t-1}^2)^{-1}$, $h_t = y_{t-1} u_t$. Assumption 5 says that both $P$ and $R$ are large; in particular, they are large relative to the forecast horizon $\tau$.

Throughout, we maintain Assumptions 1–5.

4. BASIC ASYMPOTIC RESULTS

Let

\[
\begin{align*}
\Gamma_{fh}(j) &= Ef_t h_{t-j}, & S_{fh} &= \sum_{j=-\infty}^{\infty} \Gamma_{fh}(j), & \Gamma_{hh}(j) &= Eh_t h_{t-j}, \\
S_{hh} &= \sum_{j=-\infty}^{\infty} \Gamma_{hh}(j), & V_\beta &= BS_{hh}B'.
\end{align*}
\]

$V_\beta$ is the asymptotic variance-covariance matrix of $T^{1/2}(\hat{\beta}_T - \beta^*)$.

Define $\lambda_{fh}, \lambda_{hh}$ and $\lambda = 1 - 2\lambda_{fh} + \lambda_{hh}$, all of which are scalar functions of $\pi = \lim_{T \to \infty} P/R$, as follows:

\[
\begin{align*}
\text{Sampling scheme} & & \lambda_{fh} & & \lambda_{hh} & & \lambda \\
\text{recursive} & & 1 - \pi^{-1} \ln(1 + \pi) & & 2[1 - \pi^{-1} \ln(1 + \pi)] & & 1 \\
\text{rolling, } \pi \leq 1 & & \pi & & \pi - \frac{\pi^2}{3} & & 1 - \frac{\pi^2}{3} \\
\text{rolling, } \pi > 1 & & 1 - \frac{1}{2\pi} & & 1 - \frac{1}{3\pi} & & \frac{2}{3\pi} \\
\text{fixed} & & 0 & & \pi & & 1 + \pi
\end{align*}
\]

**Lemma 4.1.** (a) $P^{-1/2} \sum \hat{g}_{t+1} \hat{\psi}_{t+1} = P^{-1/2} \sum g_{t+1} \psi_{t+1} + FB[P^{-1/2} \sum H(t)] + o_p(1)$. (b) $P^{-1/2} \sum g_{t+1} \psi_{t+1} \approx N(0, S_{ff})$. (c) $E[P^{-1} \sum H(t)\sum H(t)'] \rightarrow \lambda_{hh} S_{hh}, E[P^{-1} \sum g_{t+1} \psi_{t+1} \sum H(t)] \rightarrow \lambda_{fh} S_{fh}$.

The results for the recursive scheme follow from West (1996), and are repeated here for completeness. The results for the rolling and fixed schemes are new.

**Lemma 4.2.** $P^{-1/2} \sum \hat{g}_{t+1} \hat{\psi}_{t+1} \sim A N(0, \Omega)$, where $\Omega$ is the $(l \times l)$ matrix

\[
\Omega = S_{ff} + \lambda_{fh} (FB' S_{fh} + S_{fh} (B')' + \lambda_{hh} FV_\beta F').
\]
LEMMA 4.3.  \( P^{-1} \sum \hat{g}_{t+1} \hat{g}_{t+1}' \to_{p} \text{E} g_t g_t' \).

THEOREM 4.1.  Let \( \hat{\alpha} \) be the least squares estimator of \( \alpha \) (\( \approx 0 \)). Then \( P^{1/2} \hat{\alpha} \to_{A} N(0, \Omega) \), \( \Omega = (\text{E} g_t g_t')^{-1} \Omega (\text{E} g_t g_t')^{-1} \).

For inference, an estimate of \( V \) is required. To discuss this, we introduce some more notation. Let \( \hat{n}_{t+\tau} = \hat{\nu}_{t+\tau} - \hat{g}_{t+\tau} \hat{\alpha} \) be the least squares regression residual, \( \hat{\sigma} \) the usual scalar estimate of the standard error of the regression disturbance, and \( \hat{\Gamma}_{ff}(j) \) the \((l \times l) \) \( j \) th sample autocovariance of \( \hat{g}_{t+1} \hat{n}_{t+\tau} \):

\[
(4.4) \quad \hat{\sigma}^2 = (P - l)^{-1} \sum \hat{n}_{t+\tau}^2 = (P - l)^{-1} \sum \left( \hat{\nu}_{t+\tau} - \hat{g}_{t+\tau} \hat{\alpha} \right)^2
\]

\[
\hat{\Gamma}_{ff}(j) = P^{-1} \sum_{t=R+j}^{T} \left( \left( \hat{g}_{t+1} \hat{n}_{t+\tau} \right) \left( \hat{g}_{t+1-j} \hat{n}_{t+\tau-j} \right) \right)'
\] for \( j \geq 0 \),

\[
\hat{\Gamma}_{ff}(j) = \hat{\Gamma}_{ff}(-j)'
\] for \( j < 0 \).

THEOREM 4.2.  (a) \( \hat{\sigma}^2 \to_{p} \sigma^2 \equiv \text{E} \nu_t^2 \), \( \hat{\sigma}^2 (P^{-1} \sum \hat{g}_{t+1} \hat{g}_{t+1}')^{-1} \to_{p} \sigma^2 (\text{E} g_t g_t')^{-1} \),

(b) \( \hat{\Gamma}_{ff}(j) \to_{p} \Gamma_{ff}(j) \), \( (P^{-1} \sum \hat{g}_{t+1} \hat{g}_{t+1}')^{-1} \hat{\Gamma}_{ff}(0)(P^{-1} \sum \hat{g}_{t+1} \hat{g}_{t+1}')^{-1} \to_{p} (\text{E} g_t g_t')^{-1} \Gamma_{ff}(0)(\text{E} g_t g_t')^{-1} \).

(c) Let \( K(x) \) be a kernel such that for all \( x \), \( |K(x)| \leq 1 \), \( K(x) = K(-x) \), \( K(0) = 1 \), \( K(x) \) is continuous for all \( x \), and \( \int_{-\infty}^{\infty} |K(x)| dx < \infty \). For some bandwidth \( M \) and some constant \( a \), \( 0 < a < 1/2 \), suppose \( (M/P^a) \to 0 \) and, if \( \pi = \infty \), \( (M/P^a) \to 0 \). Then \( \hat{S}_{ff} = \sum_{j=-p+1}^{p-1} K(j/M) \hat{\Gamma}_{ff}(j) \to_{p} S_{ff} \), and \( (P^{-1} \sum \hat{g}_{t+1} \hat{g}_{t+1}')^{-1} \hat{S}_{ff}(P^{-1} \sum \hat{g}_{t+1} \hat{g}_{t+1}')^{-1} \to_{p} (\text{E} g_t g_t')^{-1} S_{ff} (\text{E} g_t g_t')^{-1} \).

Note that Theorem 4.2 assumes that the least squares residual \( \hat{n}_{t+\tau} \) is used in estimating \( \hat{\sigma}^2 \) and \( \hat{\Gamma}_{ff}(j) \). Since \( \alpha = 0 \) the asymptotic results are unchanged if one replaces \( \hat{n}_{t+\tau} \) with the left-hand side variable \( \hat{\nu}_{t+\tau} \); our formal analysis and our simulation results below both use \( \hat{n}_{t+\tau} \) because that is what will be used by standard computer programs.

Part (a) of Theorem 4.2 considers the textbook estimator of the least squares covariance matrix, and part (b) a heteroskedasticity consistent estimator that is sometimes referred to as the White (1980) covariance matrix estimator. In part (c), a nonparametric estimator is described, under conditions similar to those in Andrews (1991) or Newey and West (1994). So one can use kernels such as the Bartlett, in which \( \hat{S}_{ff} = \hat{\Gamma}_{ff}(0) + \sum_{j=1}^{M} \left( 1 - (j/M) \right) \left[ \hat{\Gamma}_{ff}(j) + \hat{\Gamma}_{ff}(j)' \right] \) with \( M \to \infty \) at a suitable rate, or the Quadratic Spectral. From part (b), if \( \hat{\Gamma}_{ff}(j) = 0 \) for \( j \geq \tau \), as will typically be the case, another estimator that is consistent for \( S_{ff} \) is the truncated estimator; here, \( \hat{S}_{ff} = \hat{\Gamma}_{ff}(0) + \sum_{j=-\tau}^{M} \left[ \hat{\Gamma}_{ff}(j) + \hat{\Gamma}_{ff}(j)' \right] \).

Theorem 4.2 says that some sample moments are consistent for the analogous population moments. But inspection of Theorem 4.1 indicates that use of these estimators may not produce a consistent estimate of \( V \). To illustrate, consider a simple setup in which \( \tau = 1 \) and \( \nu_{t+1} \) is i.i.d. and independent of current and past \( g_{t+1} \). Then \( E(\nu_{t+1} g_{t+1}) = 0 \) and \( E(\nu_{t+1} g_{t+1} g_{t+1}') = E(\nu_{t+1}^2 g_{t+1} g_{t+1}') = S_{ff} \). The least squares estimator of the regression covariance matrix is
\( \hat{\sigma}^2(P^{-1} \Sigma \hat{g}_{t+1} \hat{g}'_{t+1})^{-1} \). From Theorem 4.2, this estimator converges in probability to 
\( \sigma^2(E_\gamma g_t g_t')^{-1} \equiv E\nu_t^2(E_\gamma g_t')^{-1} \). From Lemma 4.1(b) and the proof of Lemma 4.3, this is 
the covariance matrix that is applicable in the counterfactual case in which \( \beta^* \) is known, and one regresses 
\( v_{t+\tau}(\beta^*) \) on \( g_{t+\tau}(\beta^*) \). But since \( \beta^* \) is not known, we see 
from Theorem 4.2 that the asymptotic variance of \( P^{1/2} \hat{\alpha} \) is not 
\( E\nu_t^2(E_\gamma g_t')^{-1} \) but 
\( (E_\gamma g_t')^{-1} \Omega (E_\gamma g_t')^{-1} = E\nu_t^2(E_\gamma g_t')^{-1} + ((E_\gamma g_t')^{-1}[\lambda_{fb}(FBS_{fb} + S_{fb}B'F') + \lambda_{hh} FV_0 F']^{-1}) \). 
The additional terms in braces are ones that result from 
uncertainty about \( \beta^* \). In this example and more generally, use of the usual 
regression formulas may result in asymptotically invalid tests.

If these formulas are instead to result in asymptotically valid tests, we must have 
\( S_{ff} = \Omega \). This condition implies that the asymptotic distribution of \( \hat{\alpha} \) does not depend on uncertainty about \( \beta^* \): the distribution of \( P^{1/2} \hat{\alpha} \) is identical to that of the 
estimator obtained by regressing \( v_{t+\tau}(\beta^*) \) on \( g_{t+\tau}(\beta^*) \) in the hypothetical case in which \( \beta^* \) is known. Two simple conditions are sufficient to imply \( S_{ff} = \Omega \). One is 
\( F = E\delta f_1(\beta^*)/\partial \beta = E[g_{t+\tau}(\beta^*) \partial v_{t+\tau}(\beta^*)/\partial \beta] = 0 \). This is essentially a condition 
that there is block diagonality in the asymptotic variance-covariance matrix for the 
estimators of \( \beta^* \) and \( E_{f_{t+\tau}} = E_{g_{t+\tau}} v_{t+\tau} \). This condition occasionally applies in 
practice, for example in testing for first-order serial correlation with strictly exogenous 
predictors. But since such examples are uncommon, we do not further discuss 
this condition.\(^4\)

A second condition sufficient for \( \Omega = S_{ff} \) is \( \pi = \lim_{T \to \infty} P/R = 0 \), because this 
implies \( \lambda_{fb} = \lambda_{hh} = 0 \). When \( \pi = 0 \), the limiting ratio of the size of the prediction 
sample to that of the regression sample is zero. As noted informally by Chong and 
Hendry (1986) in the context of encompassing tests, one can then act as if \( \beta^* \) is 
known. The practical implication is that if \( P/R \) is small, it may be safe to use the 
usual regression statistics. How small \( P/R \) must be depends on the data and the 
tests; in our simple Monte Carlo experiment, the lowest value of \( P/R \) was 1/7, and 
that was not sufficiently small to always make it harmless to ignore error in 
estimation of \( \beta^* \).

The next section discusses ways to obtain asymptotically valid test statistics, even 
when \( S_{ff} \neq \Omega \).

5. obtaining asymptotically valid test statistics

Throughout this section, we assume that we have an estimator of \( S_{ff} \) that satisfies 
\( \hat{S}_{ff} \to_p S_{ff} \). Theorem 4.2 describes how to obtain such an estimator. In addition, for 
\( \lambda = \lambda(\pi) \) defined in (4.2), define

\[ \hat{\lambda} = \lambda(\hat{\pi}), \quad \hat{\pi} = P/R. \]

For the recursive scheme, \( \hat{\lambda} = 1 \) for all \( \pi \), for the fixed scheme \( \hat{\lambda} = 1 + (P/R) \), and 
so on. Clearly, \( \hat{\lambda} \to \lambda \).

\(^4\) See West (1996) and McCracken (1998) for further discussion of the conditions under which 
\( F = 0 \).
COROLLARY 5.1. Suppose that

\[ S_{ff} = -\frac{1}{2} (FBS_{fh} + S_{fh} B' F') = FV F'. \]

Then \( \tilde{\lambda}(P^{-1} \sum \tilde{g}_{t+1} \tilde{g}'_{t+1})^{-1} \tilde{S}_{ff} (P^{-1} \sum \tilde{g}_{t+1} \tilde{g}'_{t+1})^{-1} \rightarrow_p V = \lambda(E_{\tilde{g}_t \tilde{g}_t'})^{-1} S_{ff} (E_{\tilde{g}_t \tilde{g}_t'})^{-1}, \)

where \( P^{1/2} \tilde{\alpha} \sim_A N(0, V). \)

Condition (5.1) implies that \( \Omega \) (defined in (4.3)) is equal to \( \lambda S_{ff} \), and Corollary 5.1 then follows directly from Theorem 4.1. Condition (5.1) might seem unlikely. But in fact, as detailed below, in certain linear models it holds for tests for: (1) mean prediction error and for efficiency, under general conditions, and (2) tests for encompassing and zero first-order serial correlation when the sampling scheme is recursive and the forecast error is conditionally homoskedastic.

Upon comparing Corollary 5.1 and Lemma 4.1(b), we see that when the conditions of Corollary 5.1 hold, uncertainty about \( \beta^* \) simply introduces a factor of \( \lambda \) into the asymptotic variance of \( P^{1/2} \tilde{\alpha} \). For the recursive sampling scheme, \( \lambda = 1 \), so error in estimation of \( \beta^* \) is asymptotically irrelevant: the variance of such estimation error \( = \lambda_{kh} FV F' \) is exactly offset by \( -\lambda_{fh} (FBS_{fh} + S_{fh} B' F') \), which is the covariance between (1) such error, and (2) error that would be present even if (counterfactually) \( \beta^* \) were known. For the fixed scheme, \( \lambda > 1 \), so failure to adjust will result asymptotically in \( t \) - and chi-squared statistics that are too small and thus in too many rejections at any specified significance level. For the rolling scheme, \( \lambda < 1 \), so failure to adjust will result asymptotically in too few rejections at any specified significance level. Further, in any finite sample, the adjustment by \( \tilde{\lambda} \) by construction increases \( t \) - and chi-squared statistics for the fixed scheme, and decreases them for the rolling scheme.

When condition (5.1) does not hold, uncertainty about \( \beta^* \) usually results in greater complications. To handle these, we propose the augmented regression (2.3), which we repeat here for convenience:

\[ \bar{\alpha}_{t,t+\tau} = \tilde{g}_{t+1} \alpha + \tilde{g}_{2t+1} \alpha_2 + \text{disturbance} = \tilde{g}_{t+1} \alpha_0 + \text{disturbance}, \]

THEOREM 5.1. Let \( g_{2t+1} (\beta^*) = (g'_{t+1}, g'_{2t+1}, Y) \) for a \( (r \times 1) \) vector \( g_{2t+1} \) defined as either (a) \( g_{2t+1} = \partial v_{t+\tau} / \partial \beta \) \( (r = k) \) or (b) \( g_{2t+1} = Z_{t+1} \) for a vector of variables \( Z_{t+1} \) that satisfies \( \partial v_{t+\tau} (\beta^*) / \partial \beta = G_{2} (\beta^*) Z_{t+1} \), \( G_{2} (\beta^*) \) a \( (k \times r) \) non-stochastic matrix. Define \( \tilde{f}_{t+\tau} = \tilde{g}_{t+1} v_{t+\tau} \). Suppose that for one of the definitions of \( g_{2t+1} \), Assumptions 1, 2, and 4 are satisfied when \( \tilde{f}_{t+\tau} \) and \( \tilde{g}_{t+1} \) replace \( f_{t+\tau} \) and \( g_{t+1} \).

Continue to maintain Assumptions 3 and 5 as well. Let \( S_{ff} \) and \( S_{fh} \) be defined as in equation (4.1), \( \tilde{F} \) as in equation (3.2), with \( \tilde{f}_{t+\tau} \) replacing \( f_{t+\tau} \). Let \( \tilde{\Omega} = S_{ff} + \lambda_{fh} (FBS_{fh} + S_{fh} B' F') + \lambda_{kh} FV F' \). Let \( \tilde{\alpha} = (\tilde{g}_{t+1} \tilde{g}_{t+1}')^{-1} (\sum \tilde{g}_{t+1} \bar{\alpha}_{t+\tau}) \) be the result of a regression of \( \bar{\alpha}_{t+\tau} \) on \( \tilde{g}_{t+1} \), with \( \tilde{\alpha} \) the first \( l \) elements of \( \tilde{\alpha} \). Then \( P^{1/2} \tilde{\alpha} \sim_A N(0, V) \), \( V \) the \( (l \times l) \) matrix in the upper-left-hand corner of \( (E_{\tilde{g}_t \tilde{g}_t'})^{-1} S_{ff} (E_{\tilde{g}_t \tilde{g}_t'})^{-1}. \)

Theorem 5.1 states that conventional regression output can be used. From Theorem 4.2, conventional regression programs consistently estimate $\hat{S}$. So, for example, if $\tau = 1$ and $\hat{u}_{t+1}$ is a textbook error—conditionally homoskedastic and serially uncorrelated—for inference one can use the $l \times l$ matrix in the upper-left-hand corner of $\hat{\Sigma}^{-1}(P^{-1} \sum \hat{g}_{t+1} \hat{g}_{t+1}^T)^{-1}$, $\hat{\sigma}$ the usual least squares estimate of the standard error of the regression disturbance that is defined in Theorem 4.2(a). More generally, if $\tau > 1$ or there is conditional heteroskedasticity, heteroskedasticity and autocorrelation consistent covariance matrix estimators may be used.

It should be noted that one of the assumptions of the theorem, that $E\hat{g}_t \hat{g}_t^T$ is of full rank (this is Assumption 1(e)) is not always innocuous. With tests of mean prediction error or of efficiency in linear models, for example, the rank condition will fail for either definition of $\hat{g}_t$. For these tests, the computationally convenient test that we propose is the one described in Corollary 5.1.

On the other hand, the condition typically is satisfied in tests for zero serial correlation of one step ahead prediction errors and for encompassing tests. For univariate ARMA models, one will augment with $\partial u_{t+1}/\partial \beta$ evaluated at $\hat{\beta}$, for linear simultaneous equations models with the vector of predetermined variables.

To prevent confusion, we emphasize that Theorem 5.1 does not say that one can use the usual regression output for inference about $\alpha_2$, the coefficients on $g_{2t+1}$. It is true that $\hat{\alpha}_2$ converges in probability to zero. But in general the usual regression output will not consistently estimate the asymptotic variance-covariance matrix, as discussed in Section 4.

6. FOUR COMMON TESTS

In this section and the next, we consider the four common tests listed in Section 2: mean prediction error, efficiency, first-order serial correlation, and encompassing. For conciseness and clarity, we limit our formal statements to one step ahead prediction errors ($\tau = 1$) in a model estimated by least squares. We comment in Section 7 on generalizations to predictions from the reduced form of linear simultaneous equations models or from univariate ARMA models, and to multiperiod predictions. This section lays out the setup. The next section presents results.

The model is

$$y_t = x_t^T \beta^* + u_t,$$

(6.1)

where $y_t$ and $u_t$ are scalars, $x_t$ and $\beta^*$ are $(k \times 1)$. The sample counterpart of $u_{t+1}$ is computed as

$$\hat{u}_{t+1} = y_{t+1} - x_{t+1} \hat{\beta}_t.$$

(6.2)

For the encompassing test, we need to describe as well the encompassed model. This will require redefining $\beta^*$. Model ‘1’ is the encompassing model, and ‘2’ the encompassed model. Let $\beta^* = (\beta^*_{1t}, \beta^*_{2t})$, where $\beta^*_{1t}$ is $(k_1 \times 1)$, $k = k_1 + k_2$, with the model $i$ prediction dependent only on $\beta^*_{1t}$. Let $x_{2t}$ be the vector of predeter-
mined variables in model 2, \( y_t = x'_{2t} \beta^*_x + u_{2t} \). The null is that \( \mu_{t+1} \) is uncorrelated with \( x'_{2t+1} \beta^*_x \), the forecast from model 2.

Along with Assumption 5 (i.e., \( P \rightarrow \infty, R \rightarrow \infty \)), we assume

**Assumption (*)**. (a) \( x_t \) includes a constant. (b) \( E(u_t | x_t, x_{t-1}, \ldots, u_{t-1}, u_{t-2}, \ldots) = 0 \) (for the encompassing test, \( E(u_t | x_t, x_{2t}, x_{1t-1}, x_{2t-1}, \ldots, u_{t-1}, u_{2t-1}, u_{t-2}, \ldots) = 0 \)). (c) For \( g_t \) and \( \tilde{g}_t \), defined in Table 1, \( E g_t^2 > 0 \) and \( E g_t \tilde{g}_t \) is of full rank.

(d) Let \( h_t(\beta^*) = x'_{t+1} h_t \) (for the encompassing test, \( h_t = (x'_{t+1} x'_{2t+1}) \)). The estimate \( \hat{\beta}_t \) satisfies \( \hat{\beta}_t - \beta^* = B(t) h(t) \), where \( B(t) = (k \times k) \) and \( h(t) = (k \times 1) \), with \( B(t) \) and \( h(t) \) defined as follows. (i) \( B(t) = (t^{-1} \sum x_t x'_t)^{-1} \) (recursive), \( B(t) = (R^{-1} \sum x_t x'_t)^{-1} \) (rolling or fixed). For the encompassing test, \( B(t) \) is block diagonal with analogously defined \( B_s(t) \) on the diagonals. (ii) \( h(t) = (t^{-1} \sum x_t h_{t}^\beta)^{-1} \) (recursive) or \( h(t) = R^{-1} \sum x_t h_{t}^\beta \) (rolling or fixed). (iii) \( E v_t^2 > 0 \), and \( E x'_t x_t \) and \( E x'_t v_t \) are positive definite (for the encompassing test, the same holds for model 2). (e) Let \( w_t = (x'_t, v_t) \).

For some \( d > 1 \), \( \sup_t E \|w_t\|^d < \infty \). (ii) \( w_t \) is strong mixing, with mixing coefficients of size \( -3d/(d-1) \). (iii) \( w_t \) is fourth-order stationary. For the encompassing test, the same holds for \( w_t = (x'_t, v_t, x'_{2t}, v_{2t}) \).

The ‘low level’ assumption (**) may be shown to imply the ‘high level’ Assumptions 1–4, as well as the validity of the null hypotheses of zero mean prediction error, zero serial correlation, and so forth. As well, part (c) of Assumption (**) follows from the other parts for mean prediction error and serial correlation; as long as \( \beta^* \neq 0 \) part (c) follows as well for efficiency. For encompassing tests, part (c) follows from the mild additional condition that the prediction from the encompassed model does not lie in the linear span of the regressors from the encompassing model.\(^5\)

**7. Obtaining Regression-Based Test Statistics for the Four Common Tests**

Column (2) of Table 1 lists the scalar right-hand side variable in the simplest version of these tests.

**Theorem 7.1.** (a) For \( g_t \) defined as in one of the rows of Table 1, let \( \hat{\alpha} = (\sum \tilde{g}_t^2)^{-1}(\sum \tilde{g}_t x_t \tilde{g}_t^2) \). (i) For mean prediction error or efficiency, \( P^{1/2} \hat{\alpha} \sim_d N(0, V), V = \lambda (E g_t^2)^{-1} E v_t^2 g_t^2 \). (ii) Let the sampling scheme be recursive, and suppose that the underlying disturbance \( v_t \) is conditionally homoskedastic, \( E(v_t^2 | x_t) = E v_t^2 \) (for encompassing, assume \( E(v_t^2 | x_t, x_{2t}) = E v_t^2 \) and \( E(v_{2t}^2 | x_t, x_{2t}) = E v_{2t}^2 \)). Then for any one of the four tests in the table, \( P^{1/2} \hat{\alpha} \sim_d N(0, V), V = \sigma^2 (E g_t^2)^{-1} \). (b) For encompassing or first-order serial correlation, augment the regression as indicated in Table 1, and regress \( v_{t+1} \) on \( \tilde{g}_{t+1} \) and \( \tilde{g}_{2t+1} \). Let \( \hat{\alpha} \) be the first element of the resulting coefficient vector. Then \( P^{1/2} \hat{\alpha} \sim_d N(0, V), V \) the (1, 1) element in \( (E \tilde{g}_t \tilde{g}_t^2)^{-1} E v_t^2 \tilde{g}_t \tilde{g}_t^2 \).\(^5\)

\(^5\) Note that this last condition rules out tests of nested (rather than nonnested) models. Such tests are in Ashley et al., (1980) and Clark (1997). An insightful referee has pointed out that some of our results do extend to nonnested models; to conserve space, we do not consider such models here.

*The model is $y_{t+1} = x_{t+1}' \beta + \nu_{t+1}$, where $y_{t+1}$ and $\nu_{t+1}$ are scalars, $x_{t+1}$ is a vector, and $\beta$ is the unknown parameter vector. In the AR(1) example of Section 2, this specializes to $y_{t+1} = y_t \beta + \nu_{t+1}$. The left-hand side variable is a one step ahead prediction error, $\hat{\beta}_{t+1} = y_{t+1} - x_{t+1}' \hat{\beta}_t$. The simpler regression analyzed in Sections 6 and 7 is one in which $\hat{\theta}_{t+1} = g_{t+1}(\hat{\beta}_t)$ (column (2)) is the sole regressor; the more complicated regression is one in which $\hat{\theta}$ (column (4)) is the vector of regressors. See Sections 6 and 7 of the paper for more detail.

Table 2 summarizes when and how to adjust.

Comments. 1. In part (a(i), asymptotically valid test statistics require scaling the usual covariance matrix by $\hat{\lambda}$ (which means no adjustment for the recursive scheme, for which $\hat{\lambda} = 1$). In parts (a(ii) and (b), no special adjustment is needed.

2. For the recursive scheme, the difference between the assumptions in (a(i) and (a(ii) is that (a(i) allows conditional heteroskedasticity of the prediction error, (a(ii) does not. The covariance matrix in part (i) reduces to that in part (ii) if there is no conditional heteroskedasticity. If there is conditional heteroskedasticity, tests for encompassing and first-order serial correlation will be missized if the inference is based on the covariance matrix given in part (a(i)).

3. While not stated formally, the results in part (a) continue to apply when a constant is included in the regression. Valid $t$- and chi-squared tests require merely rescaling the usual covariance matrix.

4. For mean prediction error, the formula for $V$ in part (a) (i) simplifies to $\lambda E\nu_t^2$. For encompassing and serial correlation, under conditional homoskedasticity the formula for $V$ in part (b) reduces to $E\nu_t^2(\hat{E}\nu_t \hat{\nu}_t)'^{-1}$.

5. Zero mean prediction error seems to be the only one of these tests that is often done for multistep horizons (e.g., Meese and Rogoff 1983). For a reduced form which is a first-order VAR, we have established that the results in part (a) still apply, with $\lambda \sum_{r=1}^{R-1} E\nu_t \nu_{t-r}$ replacing $\lambda E\nu_t^2$ as the asymptotic variance-covariance matrix.

6. A vector of sample mean prediction errors is also asymptotically normal with the variance-covariance matrix being the usual one, multiplied by $\lambda$.

7. Suppose that $\beta^*$ is estimated from the structural equations of a linear simultaneous equations model, with the reduced form used for predictions and prediction errors. Under some additional conditions, the results in Theorem 7.1 still obtain.

8. Suppose predictions are made from a univariate ARMA model that is estimated by nonlinear least squares or an asymptotically equivalent technique. Then condition (5.1), which underlies Theorem 7.1(a), continues to hold for mean predic-

*(i) The model is $y_{t+1} = x_{t+1}'\beta + \nu_{t+1}$, with $\nu_{t+1}$ serially uncorrelated. The prediction horizon is one period ($\tau = 1$). The regression run is one with $\hat{\nu}_{t+1}$ on the left-hand side, as described in Table 1. This table describes how and when to adjust the usual least squares standard errors to account for uncertainty about $\beta$.

(ii) The table assumes $\tau > 0$, $\pi$ is the limiting value of $P/R$, where $P$ is the number of predictions, $R$ the size of the smallest regression sample. When $\pi = 0$, no adjustment is needed, for any of the tests in the table.

(iii) In panels C and D, 'conditionally homoskedastic' means $E\nu_{t+1}^2 x_{t+1}'x_{t+1} = E\nu_{t+1}^2 E\nu_{t+1} x_{t+1}'x_{t+1}$, 'conditionally heteroskedastic' allows the possibility that $E\nu_{t+1}^2 x_{t+1}'x_{t+1} \neq E\nu_{t+1}^2 E\nu_{t+1} x_{t+1}'x_{t+1}$.

(iv) Panel D allows $E\nu_{t+1} x_{t+1} \neq 0$, as is typically the case in time series applications. If $E\nu_{t+1} x_{t+1} = 0$, no correction is needed, for any of the schemes, and whether or not $\nu_{t+1}$ is conditionally heteroskedastic.

8. MONTE CARLO EVIDENCE

Here we present a simple Monte Carlo experiment. Our aim is to get a feel for whether our proposed adjustments to the usual least squares statistics are likely to be useful in practice, and, more generally, whether our asymptotic approximation...
might yield well-sized test statistics. It turns out that while our approximation does usually work well, the rolling sampling scheme does sometimes require unusually large samples sizes to generate accurate test statistics.

The experiment we present involved 5000 repetitions. Each repetition required generating 201 data points (200 excluding an initial condition). (Some additional experiments reported briefly in Table 6 and in detail in the additional Appendix involved 1000 repetitions of samples of size 1601.) Each of these 5000 artificial samples of size 200 were split into 15 different regression (R) and prediction (P) samples. The values of P and R were: $R = 25, P = 25, 50, 100, 150, 175$; $R = 50, P = 25, 50, 100, 150$; $R = 100, P = 25, 50, 100$; $R = 150, P = 25, 50$; $R = 175, P = 25$—15 combinations in all. This range for $P/R$ (from 1/7 to 7), as well as the values of $T = P + R - 1$, seem broad enough to include most relevant empirical work. For a given $(P, R)$ pair, the $(P \times 1)$ vector of prediction errors used on the left-hand side of the regression tests was $\{\hat{v}_t\}_{t=1}^R$, $t = R, \ldots, R + P - 1$.

For each pair of $R$ and $P$, the first $R + P$ observations of each sample of size 200 were used. So $R = 50, P = 100$ and $R = 100, P = 50$, for example, used the same 150 observations, but began the out-of-sample exercise at different points. This means, for example, that for the recursive scheme the 50 prediction errors used in the $R = 100, P = 50$ sample were identical to the last 50 in the $R = 50, P = 100$ sample.

A recent literature has emphasized the inaccuracy of conventional asymptotic approximations in some time series environments. Examples from our own work include Newey and West (1994) and West and Wilcox (1996). We suspect that our out-of-sample procedures will also work poorly in such environments. To give as clear as possible a sense for whether our procedures might work well, we consider a data generating process and regression that to our knowledge has in-sample behavior that is reasonably well approximated by conventional asymptotic theory. This process is a zero-mean AR(1) with i.i.d. normal disturbances and an autoregressive parameter that is not close to the unit circle,

$$y_t = \beta^* y_{t-1} + \nu_t, \quad \beta^* = 0.5, \quad \nu_t \sim N(0, 1).$$

In each of the 5000 samples, $y_0$ was drawn from its unconditional $N(0, (1 - \beta^{*2})^{-1})$ distribution, and $y_1, \ldots, y_{200}$ were generated recursively using (8.1) and pseudo-random draws of $\nu_t$.

In each sample, and for each $P$ and $R$, four hypothesis tests were conducted for one step ahead ($\tau = 1$) predictions: mean prediction error, efficiency, zero serial correlation, and encompassing. For the last test the alternative model was $y_t = \beta_2 y_{t-2} + \nu_{2t}$. This was estimated by least squares, so $\beta_2 = (E\hat{y}_{t-2}^2)^{-1}E\hat{y}_{t-2}y_t$. The introduction of the second lag meant that some regression samples were one observation smaller than the 'R' reported in the table.

We report tests of nominal size 0.05. Tests of nominal size 0.01 and 0.10 worked equally well, and tests with larger sample sizes worked better; see the additional Appendix. All regression tests included a constant term, since these typically would be included in practice. Apart from adjustment by a factor of $\hat{\lambda}$ in regressions in which our theory calls for such an adjustment, the usual least squares covariance matrix was used—that is, we did not use a heteroskedasticity consistent covariance matrix estimator.

* The DGP is a univariate AR(1); see text for details. For the indicated values of $P$ and $R$, $\hat{\epsilon}_{t+1}$ (the one step ahead prediction error) was regressed on a constant for $t = R, \ldots, R + P - 1$. Panels B1 and B2 report the fraction of the 5000 simulations in which the conventionally computed $t$-statistic on the coefficient on the constant term was greater than 1.96 in absolute value. Panels A1–A3 report the same, when the conventionally computed $t$-statistic is divided by the square root of $\lambda$.

Table 3A presents results for mean prediction error. Tests for the recursive scheme work quite well, with nominal 0.05 tests having actual sizes between 0.046 and 0.057. Our approximation does not work as well for the rolling and fixed schemes, although performance is perhaps tolerable for $P/R \leq 1$, and is quite good for $P/R \leq 0.5$.

Table 3B presents results when the least squares $t$-statistic is used, without dividing as we suggest by $\sqrt{\lambda}$. Recall that by construction: (1) the rolling scheme must have lower actual size and the fixed scheme higher actual size when our adjustment for error in estimation of $\beta^*$ is ignored; (2) the adjustment is smaller the smaller is $P/R$. Panels A3 and B2 indicate that for the fixed scheme, our adjustment improves the size for all $P/R$. The difference is perhaps not large for small $P/R$ (e.g., for $P = 25$, $R = 100$, our test statistic yields a size of 0.058, the unadjusted a size of...
but it is dramatic for large $P/R$ (for $P = 175$, $R = 25$, our test statistic has a size of 0.099 versus 0.523 for the unadjusted test statistic).

For the rolling scheme, the comparison is not as clear cut, since our test statistic typically rejects too infrequently (actual size > 0.05), while the unadjusted typically rejects too often (actual size < 0.05). While we do not have a precise loss function for under- versus over-rejection, our own gut feeling is that we would rather have a nominal 0.05 test have a probability of rejecting of say 7.4 per cent ($P = 50$, $R = 25$, our test statistic) than of 0.3 per cent (unadjusted test statistic), all other things being equal. In this sense, our test statistics perform better for the rolling scheme as well. But we recognize that other researchers may have different loss functions, at least in some applications.

Table 4 has the results for the efficiency test. For the recursive and fixed schemes, our procedure seems to be a little more accurately sized than it was for mean

* The DGP is a univariate AR(1); see text for details. Let $\hat{\beta}_{2t}$ denote the least squares estimate of a regression of $y_t$ on $y_{t-2}$ using the same sample as that used to obtain $\hat{\beta}$. For the indicated values of $P$ and $R$, $\hat{\epsilon}_{t+1}$ (the one step ahead prediction error) was regressed on a constant and $y_{t-1} \hat{\beta}_{2t}$ for $t = R, \ldots, R + P - 1$. Panels A1, B1, and B2 report the fraction of the 5000 simulations in which the conventionally computed $t$-statistic on the coefficient on $y_{t-1} \hat{\beta}_{2t}$ was greater than 1.96 in absolute value. Panels A2 and A3 report the same, when $y_t$ was included as a third regressor.

prediction error. But for these two schemes the remarks made in connection with Table 3 generally apply here as well.

The rolling scheme, however, performs quite poorly for $P/R > 1$. In fact, for $P/R > 1$, the over-rejection is so extreme that failure to adjust generally improves the test statistic. For example, for $P = 50$, $R = 25$, panel A2 indicates that our procedure had an actual size of 43 per cent, while panel B1 indicates that use of the usual least squares test statistic yielded a size of 7.2 per cent.

Tables 5 and 6 indicate that for the encompassing test and the test for zero first-order serial correlation, the Table 4 results apply qualitatively: For the recursive and the fixed schemes, our test statistics work adequately, and dominate the unadjusted test statistic. But for the rolling scheme our test statistic works poorly.

In Tables 4–6, the rolling scheme worked quite poorly for $P/R > 1$. To see how large a sample is required for tolerable accuracy of the asymptotic approximation,
we generated 1000 samples of size 1601; we report here certain results with samples of size up to 1201 (full details are in the additional Appendix). We controlled the seed to the random number generator so that the first 201 observations in each sample were the same as in Tables 3–6. We then conducted the efficiency test for some larger sample sizes, holding \( P/R \) fixed at 2 and at 4. The results are in Table 7. As may be seen, by the time the sample size hits 1200, the result for \( P/R = 2 \) is

\[

\text{A. (P/R) = 2} & \text{P = 50, R = 25} & \text{P = 100, R = 50} & \text{P = 200, R = 100} & \text{P = 400, R = 200} & \text{P = 800, R = 400} \\
 & 0.430 & 0.232 & 0.108 & 0.091 & 0.069 \\
\text{B. (P/R) = 4} & \text{P = 100, R = 25} & \text{P = 400, R = 100} & \text{P = 800, R = 200} \\
 & 0.939 & 0.409 & 0.229 \\
\end{array}
\]

* See notes to Table 4. The tests account for error in estimation of \( \beta^* \). The figures for \( P + R < 200 \) are repeated from Table 4.
reasonably accurate (actual size of 0.069), at least by the standards of Tables 3–6 and much other work on hypothesis testing in time series models. For \( P/R = 4 \), however, substantial missing still remains.

We conclude that our asymptotic approximation usually works reasonably well, but that for the rolling sampling scheme relatively large sample size sometimes are required.

**APPENDIX**

Notation: ‘sup,’ means ‘sup\(_{R \leq t \leq T} \);’ ‘var,’ and ‘cov’ denote variance and covariance; all limits are taken as the sample size \( T \) goes to infinity; the summation ‘\( \Sigma \)’ means ‘\( \sum_{r=R}^{T} \);’ For notational simplicity, we consider throughout the case in which \( k = 1 \) and \( l = 1 \), so that \( \beta^* \), \( g_{t+1} \) and \( f_{t+\tau} \) are scalars, and we let ‘\( f_{t+\tau, \beta_\beta} (\hat{\beta}_t) \) mean ‘\( \partial^2 f_{t+\tau, \beta} (\hat{\beta}_t) / \partial \beta^2 \).’ To save space, proofs of Lemmas A1 to A4 and parts of other proofs are put in an additional Appendix available on request from the authors.

**LEMMA A1.** Suppose \( \pi < \infty \). For \( 0 \leq a < .5 \): (a) \( \sup_{t} |P^a H(t)| \to_p 0 \); (b) \( \sup_{t} |P^a (\hat{\beta}_t - \beta^*)| \to_p 0 \).

**LEMMA A2.** (a) \( P^{-1} \sum f_{t+\tau}^2 = O_p(1) \), (b) \( P^{-1} \sum f_{t+\tau, \beta}^2 = O_p(1) \), (c) For \( \hat{\beta}_t \) satisfying \( |\hat{\beta}_t - \beta^*| \leq |\hat{\beta}_t - \beta^*| \) for \( t = R, \ldots, T \), \( P^{-1} \sum f_{t+\tau, \beta}^2(\hat{\beta}_t) = O_p(1) \).

**LEMMA A3.** Let \( \hat{\Gamma}_{ff}(j) = P^{-1} \sum_{t=R+1}^{T} \left[ \left( \hat{g}_{t+\tau} \right) \hat{v}_{t+\tau, \beta} \right] \). Then \( \hat{\Gamma}_{ff}(j) \to_p \Gamma_{ff}(j) \).

**LEMMA A4.** Under the assumptions of Theorem 4.2, and with \( \hat{\Gamma}_{ff}(j) \) defined as in Lemma A3, \( \hat{S}_{ff} = \sum_{j=-p+1}^{p-1} K(j/M) \hat{\Gamma}_{ff}(j) \to_p S_{ff} \).

**PROOF OF LEMMA 4.1.** (a) For the recursive scheme, this follows from Lemma 4.1 of West (1996). The relatively simple argument for the fixed scheme is in the additional Appendix. For the rolling scheme, expand \( f_{t+\tau, \beta} (\hat{\beta}_t) \) around \( f_{t+\tau, \beta^*} \) for \( t = R, \ldots, R + P - 1 \), and sum the results, yielding

\[
(A1) \quad P^{-1/2} \sum f_{t+\tau, \beta} (\hat{\beta}_t)
= P^{-1/2} \sum f_{t+\tau} + P^{-1/2} \sum f_{t+\tau, \beta} B(t) H(t) + P^{-1/2} \sum w_{t+\tau},
\]

for \( w_{t+\tau} = \frac{5}{2} f_{t+\tau, \beta} (\hat{\beta}_t) (\hat{\beta}_t - \beta^*)^2 \). We have \( |P^{-1/2} \sum w_{t+\tau}| \leq .5 (P^{1/4} \sup_t |\hat{\beta}_t - \beta^*|^2 (P^{-1} \sum f_{t+\tau, \beta} (\hat{\beta}_t)) \to_p 0 \) by Lemmas A1 and A2. The second term in (A1) can be written

\[
P^{-1/2} B \sum H(t) + P^{-1/2} \sum \{ F[B(t) - B] H(t) \} + P^{-1/2} \sum \{ (f_{t+\tau, \beta} - F) B H(t) \}
+ P^{-1/2} \sum \{ (f_{t+\tau, \beta} - F) [B(t) - B] H(t) \}
\]

and hence we need show that the last three terms in the above expression are \( o_p(1) \).
We will show the result for $P^{-1/2} \Sigma ([f_{t+\tau, \beta} - F] BH(t))$, the others follow from arguments similar to those for the recursive scheme (West 1996).

For notational simplicity, let $x_t \equiv (f_{t+\tau, \beta} - F)$, redefine $B_h$, as $h_t$, and let $\gamma_t \equiv E_{t} x_t h_t$. For $P < R$ (the $P > R$ case is similar) we have $|E P^{-1/2} \Sigma x_t H(t) = (P^{1/2} / R) \gamma_0 + \cdots + \gamma_{R-1}| \leq (P/R)^{1/2} R^{-1/2} \Sigma_{j=0}^{\infty} |\gamma_j| \to 0$ since $\pi < \infty$ and $\Sigma_{j=0}^{\infty} |\gamma_j| < \infty$. Then since it can be shown that Assumption 4 bounds the fourth moments of $(x_t, h_t)'$ in such a way that $\lim \var P^{-1/2} \Sigma x_t H(t) = 0$, the result follows from Chebyshev's inequality. (b) Follows from Theorem 3.1 of Wooldridge and White (1989). (c) For the recursive scheme the results are in West (1996). For the fixed scheme, $E P^{-1} \Sigma H(t) \Sigma H(R) = (P/R) E [R^{-1/2} \Sigma_{t=1}^{R} h_t (x_t)^2] \to \pi \Sigma_{h,h}$. To show that $\lambda_{jh} = 0$, let $\gamma_j = E_{t+\tau} h_{t-j}$. Then $|E P^{-1/2} \Sigma_{x_t} \Sigma_{h_{t-j}}^2| = |R^{-1} [(\gamma_{R-1} + \cdots + \gamma_0) + \cdots + (\gamma_{R+P-2} + \cdots + \gamma_{P-1})]| \leq R^{-1} \Sigma_{j=-\infty}^{\infty} |\gamma_j| \to 0$ since Assumption 4 implies $\Sigma_{j=-\infty}^{\infty} |\gamma_j| < \infty$ (Andrews 1991).

For the rolling scheme, we will sketch the result that $E P^{-1} \Sigma H(t) \Sigma H(t) \to \lambda_{jh} \Sigma_{h,h} = [(\pi - (\pi^2/3)] \Sigma_{h,h}$ for $\pi < 1$. The proofs for $\pi \geq 1$, and for $E P^{-1} \Sigma_{x_t} \Sigma_{h_{t-j}} \Sigma H(t) \to \lambda_{jh} \Sigma_{h,h}$, are conceptually similar.

With $P < R$, $\Sigma H(t)$ may be written as the sum of three terms, $\Sigma H(t) = A_1 + A_2 + A_3, A_1 = R^{-1} [h_1 + 2h_2 + \cdots + (P-1)h_{P-1}], A_2 = PR^{-1} [h_R + \cdots + h_R], A_3 = R^{-1} (P-1)h_{P+1} + \cdots + 2h_{R+P-2} + h_{R-P+1}$. It is easy to see that $\lim \var P^{1/2} A_j = \lim P (R-P+1) R^{-2} \Sigma_{j=1}^{P-1} E h_t h_{t-j} + o(1) = (\pi - \pi^2) \Sigma_{h,h}$. We will sketch the argument that shows $\lim \var P^{1/2} A_j = (\pi^2/3) \Sigma_{h,h}$. That limit $\lim \var P^{1/2} A_j = (\pi^2/3) \Sigma_{h,h}$ follows from a nearly identical argument. Since, finally, it can be shown that $\lim \cov (P^{1/2} A_j, P^{1/2} A_i) = 0$ for $i \neq j$, the result will follow.

For simplicity, assume $q = 1$. Redefine $\gamma_j$ as $\gamma_j = Eh_t h_{t-j}$, and for $|j| \leq P - 2$ define $d_j = \Sigma_{t=1}^{P-1} \Sigma_{(i+j)}$. Then

$$\var (A_j) = R^{-2} \Sigma_{j=-P+2}^{P-2} d_j \gamma_j = R^{-2} \Sigma_{j=P+2}^{P-2} \sum d_j \gamma_j - R^{-2} \sum (d_0 - d_j) \gamma_j.$$

We have $P^{1/2} d_j \gamma_j \sim (P^3/(3PR^2)) \to \pi^2/3$, and the result will follow if $P^{1/2} d_j \gamma_j \to 0$. This result may be established using $d_0 \leq \int_0^P x^2 \, dx, d_j \leq \int_{j+1}^{P} (x-j) x \, dx \to \int_0^P x^2 \, dx - \int_{j+1}^{P} (x-j) x \, dx$, solving the integrals and manipulating the result to obtain $P^{1/2} \Sigma (d_0 - d_j) \gamma_j \leq (1/3) P \Sigma |j| |\gamma_j| + o(1) \to 0$.

PROOF OF LEMMA 4.2. Let $X(T) = \Sigma [g_{t+1} \beta_{t+1} + FBH(t)]$. From Lemma 4.1, $P^{-1/2} \Sigma \hat{g}_{t+1} \beta_{t+1} = P^{-1/2} X(T) + o_p(1)$, with $\lim \var P^{-1/2} X(T) = \Omega$. Asymptotic normality then follows from Theorem 3.1 of Wooldridge and White (1989). Details are in the additional Appendix.

PROOF OF LEMMA 4.3. Follows from a mean value expansion of $g_{t+1}(\beta_t)$ around $g_{t+1}(\beta^*)$. Details are in the additional Appendix.

PROOF OF THEOREM 4.1. Follows immediately from Lemmas 4.1, 4.2 and 4.3.

PROOF OF THEOREM 4.2. (a) That $P^{-1/2} \Sigma \hat{g}_{t+1} \beta_{t+1} \to_p E \beta_{t+1}^2$ follows from Lemma 4.3. Hence we need only show that $(P-1)^{-1} \Sigma (\hat{g}_{t+1} - \hat{g}_{t+1} \beta_t)^2 \to_p E \beta_{t+1}^2$. We have
\[ (P - 1)^{-1} \sum (\hat{g}_{t,i+\tau} - \hat{g}_{t+1,i+\tau})^2 = (P - 1)^{-1} \sum \hat{g}_{t,i+\tau}^2 + [(P - 1)^{-1} \sum \hat{g}_{t,i+\tau}^2] \hat{\alpha}^2 - 2 \hat{\alpha}[(P - 1)^{-1} \sum \hat{g}_{t,i+\tau}^2] \]

That \( (P - 1)^{-1} \sum \hat{g}_{t,i+\tau}^2 \rightarrow \rho \) \( E \hat{\nu}_{t+\tau}^2 \) follows from Lemma A3. By Theorem 4.1, \( \hat{\alpha} = o_p(1) \); by Lemmas 4.2 and 4.3, \( (P - 1)^{-1} \sum \hat{g}_{t,i+\tau}^2 = O_p(1) \), \( (P - 1)^{-1} \sum \hat{g}_{t,i+\tau}^2 = O_p(1) \). The desired result now follows. (b) That \( P^{-1} \sum \hat{g}_{t,i+\tau}^2 \rightarrow \rho \) \( E \hat{\nu}_{t+\tau}^2 \) follows from Lemma A3. Hence we need only show that \( \hat{\Gamma}_{ff}(j) = P^{-1} \sum_{t=R+j}^T \hat{g}_{t+1,i+\tau} \hat{\nu}_{t+\tau-j} \rightarrow \rho \) \( E \hat{\nu}_{t+\tau}^2 \) \( \hat{\nu}_{t+\tau-j} \equiv \Gamma_{ff}(j) \) for all \( j \). For \( \hat{\Gamma}_{ff}(j) \) defined in Lemma A3, we have

\[ \hat{\Gamma}_{ff}(j) = \hat{\Gamma}_{ff}(j) + P^{-1} \sum_{t=R+j}^T \hat{g}_{t+1,i+\tau} \left( \hat{\nu}_{t+\tau-j} \right) \]

Lemma A3 shows that the first term converges in probability to \( \Gamma_{ff}(j) \); the additional Appendix shows that the second term converges in probability to zero. (c) That \( P^{-1} \sum \hat{g}_{t,i+\tau}^2 \rightarrow \rho \) \( E \hat{\nu}_{t+\tau}^2 \) follows from Lemma A3. Hence we need only show that \( \hat{\Delta}_{ff} = \sum_{t=R+j}^T K(j/M) \hat{\Gamma}_{ff}(j) \rightarrow \rho \) \( S_{ff} \). For \( \hat{\Delta}_{ff} \) defined in Lemma A4, we have \( \hat{\Delta}_{ff} = \Delta_{ff} + \sum_{t=R+j}^T K(j/M) \hat{\Gamma}_{ff}(j) \rightarrow \rho \) \( \hat{\Gamma}_{ff}(j) \). Lemma A4 shows that the first term converges in probability to \( \Delta_{ff} \); the additional Appendix shows that the second term converges in probability to zero.

**Proof of Corollary 5.1.** Follows immediately from Theorem 4.1.

**Proof of Theorem 5.1.** By definition, the \((l + r) \times k\) matrix \( \hat{F} = \hat{E} \hat{g}_{t+1,i+\tau} \hat{g}_{t+1,i+\tau}^T \); if \( g_{2t+1} = \nu_{t+\tau, \beta} \), then \( \hat{F} = (\hat{E} g_{2t+1} g_{2t+1}^T, \hat{E} g_{2t+1} g_{2t+1}^T) \), while if \( g_{2t+1} = Z_{t+1} \), \( \hat{F} = (\hat{E} g_{2t+1} g_{2t+1}^T, \hat{E} g_{2t+1} g_{2t+1}^T) \). From Lemmas 4.1 and 4.3 and Theorem 4.1,

\[ P^{1/2} \hat{\alpha} = \left( P^{-1} \sum \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau} \right)^{-1} \left( P^{-1/2} \sum \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau} \right) \]

\[ = \left( \hat{E} \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau} \right)^{-1} \left( P^{-1/2} \sum \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau} \right) + o_p(1) \]

\[ = \left( \hat{E} \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau} \right)^{-1} \left( P^{-1/2} \sum \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau} \right) + o_p(1), \]

Upon partitioning \( \hat{E} \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau} \) conformably with \( g_{t,i+\tau} \) and \( g_{2t+1} \) and using the formula for the inverse of a partitioned matrix, we find that the first \( l \) rows of the \((l + r) \times k\) matrix \( (\hat{E} \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau})^{-1} \hat{F} \) are identically zero. Since \( \hat{\alpha} \) consists of the first \( l \) components of \( \hat{\alpha} \), \( P^{1/2} \hat{\alpha} \) equals the first \( l \) rows of \( (\hat{E} \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau})^{-1} (P^{-1/2} \sum \hat{g}_{t,i+\tau} \hat{g}_{t+1,i+\tau}) \) + \( o_p(1) \), and the proof is complete.

**Proof of Theorem 7.1.** (a) (i) From Corollary 5.1, condition (5.1) is sufficient to guarantee the result. From Assumption (*), we have \( B = (\hat{E} \hat{x}_i \hat{x}_i')^{-1} \) and \( S_{h+h} = \hat{E} \hat{\nu}_i^2 \hat{x}_i \hat{x}_i' \). For mean prediction error, recall that \( x_i \) contains a constant. Without loss of generality define \( x_i = (1, \hat{x}_i') \) where \( \hat{x}_i \) is a vector of nonconstant regressors. Then \( F = -1(1, \hat{E} \hat{x}_i) \), which implies \( FB = -1(1, 0, \cdots, 0) \); the result follows since the (1, 1) elements of both \( S_{fh} \) and \( S_{hh} \) are \( S_{ff} = \hat{E} \hat{\nu}_i^2 \). For efficiency, note that \( F = -\beta^* B^{-1} \).
and hence $FB = -\beta^*$. The result then follows since $S_{ff} = \beta^* S_{hh} \beta^*$ and $S_{fh} = \beta^* S_{hh}$.

(a) (ii) For mean prediction error or efficiency, the conditional homoskedasticity assumption implies $E \hat{\delta}^2 = E \hat{\varepsilon}^2 F F^t$ and the result follows from part (i). For the other two tests, recall that for the recursive scheme $\lambda_h = 2 \lambda_f$ and thus $\Omega = S_{ff} + \lambda_h (F B S_{fh} + S_{fh} B^t F^t) + 2 \lambda_f F F^t F^t$. Hence it suffices to show $-FB S_{fh} = F F^t F$. For serial correlation, this follows since $F = -E \hat{\varepsilon}_{t-1} x_t', \quad B = (E x_t x_t')^{-1}$, $S_{hh} = E \hat{\varepsilon}^2 B^{-1}$, and $S_{fh} = -E \hat{\varepsilon} x_t'$. For encompassing this follows since $F = (-\beta_2 x_t', 0')$, $B = \text{diag}(E x_t x_t')^{-1}$, $(E x_t x_t')^{-1}$, the $(k_2 \times k_2)$ block in the upper left hand corner of $S_{hh}$ is $E \hat{\varepsilon}^2 x_t x_t'$, and $S_{fh} = \beta_2^* (E \hat{\varepsilon}^2 x_t x_t', E \hat{\varepsilon} x_t x_t')$. (b) Follows from Theorem 5.1
